#### Abstract

The Indus River/Delta system is highly dynamic, reflecting the impacts of monsoonal-driven floods and cyclone-induced storm surges, earthquakes ranging up to  $M_w=7.8$ , and inundations from tsunamis. 19<sup>th</sup> century Indus discharge was likely larger than today, but upstream seasonal spillways limited the maximum flood discharge. Upstream avulsions during the 2010 flood similarly reduced the downstream discharge, so that only 43% of the floodwaters reached the delta. The present-day Indus River is wider with larger meander wavelengths (~13 km) compared to the 4km to 8km meander wavelengths for the super-elevated historical channel deposits. The Indus River is presently affected by: 1) artificial flood levees, 2) barrages and their irrigation canals, 3) sediment impoundment behind upstream reservoirs, and 4) inter-basin diversion. This silt-dominated river formerly transported 270+ Mt/y of sediment to its delta; the now-transformed river carries little water or sediment (currently ~13 Mt/y) to its delta, and the river often runs dry. Modern-day reduction in fluvial fluxes is expressed as fewer distributary channels, from 17 channels in 1861 to just 1 significant channel in 2000. Abandoned delta channels are being tidally reworked. Since 1944, the delta has lost 12.7 km<sup>2</sup>/y of land altering a stunning 25% of the delta; 21% of the 1944 delta area was eroded, and 7% of new delta area formed. The erosion rate averaged ~69 Mt/y, deposition averaged ~22 Mt/y, providing a net loss of ~47 Mt/y particularly in the Rann of Kachchh area that is undergoing tectonic subsidence.

## Anthropocene Metamorphosis of the Indus Delta and Lower Floodplain

### Abstract

The Indus River/Delta system is highly dynamic, reflecting the impacts of monsoonal-driven floods and cyclone-induced storm surges, earthquakes ranging up to  $M_w=7.8$ , and inundations from tsunamis. The 19<sup>th</sup> century Indus discharge was likely larger than today, but upstream seasonal spillways limited the maximum flood discharge. Upstream avulsions during the 2010 flood similarly reduced the downstream discharge; only 43% of floodwaters reached the delta. The present-day Indus River is wider with larger meander wavelengths (~13 km) compared to the 4km to 8km meander wavelengths for the historical channel deposits. The Indus River is presently affected by: 1) artificial flood levees, 2) barrages, 3) sediment impoundment behind reservoirs, and 4) inter-basin diversion. The Indus formerly transported 270+ Mt/y of sediment to its delta; the river now delivers little water or sediment (currently ~13 Mt/y); the river often runs dry. Reduction in fluvial fluxes is expressed as fewer distributary channels, from 17 in 1861 to 1 significant channel in 2000. Abandoned delta channels are being tidally reworked. Since 1944, the delta has lost 12.7 km<sup>2</sup>/y of land altering 25% of the delta. Erosion averaged ~69 Mt/y, deposition averaged ~22 Mt/y, providing a net loss of ~47 Mt/y particularly in the Rann of Kachchh a tectonic subsiding area. The former river-delta system likely could not be converted back to its pre-Anthropocene state. The Indus River's self-regulating processes have not buffered these changes, and have initiated self-enhancing mechanisms. These lessons are globally applicable to other delta systems (e.g. Mississippi, Colorado, Ganges, Po, and Nile).

### Introduction

Among the world's large deltas, the Indus has been one of the more dynamic systems, reflecting its large, tectonically active mountain belt upland, the impacts of monsoonal-driven floods and cyclone-induced storm surges, nearby historical tectonic events (e.g. earthquakes ranging up to  $M_w=7.8$ ), and inundations from tsunamis. Some human interventions are ancient, dating back some 4000 years before present. However it is during the past 150 years that the river and its delta have experienced human interventions as a geomorphic factor of consequence (e.g. watershed deforestation, diversion canals, and dams, levees and barrages that today comprise the world's largest irrigation system). *This paper contrasts the evolution of the Indus River-delta system under mid-Holocene (post 6,500 yr B.P.) conditions, to its evolution through the 20<sup>th</sup> century.* In the 19<sup>th</sup> and 20<sup>th</sup> century, human impact on the Holocene river system changed to such extent that dubbing the last centuries the 'Anthropocene' is appropriate. During the Late Holocene, river avulsions both transient and permanent were normal, and multiple distributary

1  
2  
3  
4 channels fed an actively prograding tide- and wave-affected delta. Natural avulsions were still  
5  
6 occurring in the 19<sup>th</sup> century. During the present Anthropocene, flood deposition and avulsions  
7  
8 are restricted by engineering works, water and sediment flux to the coastal ocean is greatly  
9  
10 reduced, and coastal retreat, tidal-channel development, salinization of irrigated soils, and  
11  
12 saltwater intrusion have all occurred. *We seek to quantify these changes and infer their proximal*  
13  
14 *causation. In particular, how has the long-term 'harnessing' of this river affected its large-scale*  
15  
16 *geometry, and its floodplain deposition; how has sediment and water starvation affected the delta*  
17  
18 *fringe?* The enormity of this geo-engineering experiment offers many lessons. Our analysis  
19  
20 includes data on channel patterns from geo-located historical maps over the 19<sup>th</sup> and 20<sup>th</sup> century  
21  
22 with reference to earlier times, satellite imagery collected during the last 35 years, and satellite-  
23  
24 based flood inundation surveys.  
25  
26  
27

### 28 29 **Environmental Setting**

30  
31  
32 The Indus fluvio-deltaic lowlands receive water, sediment and nutrients from the 1 M km<sup>2</sup> Indus  
33  
34 drainage basin. Before human intervention in the 20<sup>th</sup> century, average discharge for the 2900 km  
35  
36 long Indus River was 3000 m<sup>3</sup>/s and it carried a silty sediment load of at least 250 Mt/y (Milliman  
37  
38 et al., 1984). The more pristine Indus had an unusually high suspended sediment concentrations  
39  
40 ~3 kg/m<sup>3</sup> (Holmes, 1968). Peak discharge can exceed 30,000 m<sup>3</sup>/s, commonly during July-  
41  
42 September, and are driven by heavy monsoon rains. Annual rainfall ranges from frontal  
43  
44 Himalayan values of almost 200 cm to only ~23 cm on the Indus plain, and even lower values (~9  
45  
46 cm) over the Indus Delta.  
47  
48

49  
50 Tectonics control the continental valley geometry of the Indus, and the main course of the Indus  
51  
52 migrated to a generally more westward located course over the past 5000 years (Kazmi, 1984).  
53  
54 The legendary Saraswati River, whose probable ancient course in the Thar Desert is marked by  
55  
56 numerous abandoned archaeological sites, may have once supplemented the Indus delta (Oldham,  
57  
58 1886; 1893; Stein, 1942; Lal and Gupta 1984; Mughal 1997; Giosan et al. 2012). Rather than  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 being an effect of Saraswati's loss, we speculate that a westward migration of the Indus course  
5  
6 may have a more deep seated cause, possibly associated with slow flexural uplift of the central  
7  
8 Indian plateau (Bilham et al., 2003).  
9

10  
11 The delta's climate is arid sub-tropical; the river mouth is located almost in the tropics, at 24° N  
12  
13 67°30' E. The present Indus delta is 17,000 km<sup>2</sup>; the active tidal flat area is ~10,000 km<sup>2</sup>. The  
14  
15 delta once hosted the world's largest arid mangrove forest (Inam et al, 2007). Warm coastal  
16  
17 waters (22°C on average) and summer tidal inundation result in salt deposits (Memon 2005). The  
18  
19 tidal range is 2.7m (Giosan et al 2006). Swampy areas on the delta are restricted to areas near  
20  
21 tidal channels and coastal areas that undergo tidal flooding.  
22  
23

24  
25 Although the Indus delta receives high deep-water wave energy, attenuation on the shallow shelf  
26  
27 results in lower wave energy at the coast than is typical for wave-dominated deltas (Wells and  
28  
29 Coleman, 1984). Wave measurements offshore Karachi at 20 m water-depth show a mean  
30  
31 significant wave height during the summer southwest monsoon (May–September) of ~ 1.8m with  
32  
33 a mean period of 9 s (Rizvi et al. 1988). During the winter, with offshore-directed monsoon winds  
34  
35 (October–April), significant wave height is ~ 1.2m with a period of 6.5 s (Rizvi et al., 1988).  
36  
37 Wave-driven sediment transport redistributes river-delivered sediments along the deltaic coast  
38  
39 (Wells and Coleman, 1984; Giosan et al., 2006).

## 46 **The Indus and its Lower Floodplain**

### 47 *The More Natural Indus River*

48  
49  
50  
51  
52 Recorded regional history extends back several thousand years (including annals from the time of  
53  
54 Alexander the Great c. 325 BC). Embracing ~2 millennia prior, humans certainly modified the  
55  
56 landscape: the population of the Harappan culture is estimated at ~5 million at peak, with ~1000  
57  
58 major settlements in what is now Pakistan. However, we postulate these modifications are  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 relatively minor compared to changes from 1869 onwards when artificial levees and great modern  
5 irrigation systems became established, population grew from ~25 million people to the present  
6 ~188 million (UN, 2012), and the Indus ceased to transport large quantities of freshwater and  
7 sediment to the delta and the sea. We here describe natural processes occurring in the presence of  
8 humans, but not so greatly altered by them.  
9

10  
11 The Indus floodplain (Fig. 1, 2) is between 100-200 km wide and consists of deep deposits of  
12 unconsolidated and highly permeable alluvium deposited by the Indus River and its tributaries  
13 (Kazmi, 1984). During the Holocene between ~300 and 1100 Mt/y were delivered by the Indus  
14 River to its lower alluvial plain and delta (Clift and Giosan, 2013). Immediately before the 20<sup>th</sup>  
15 century damming activities started, the Indus deposited ~60% of its total load along its lower  
16 alluvial plain: with more than 600 Mt/y entering the alluvial plain and only 250 Mt/y reached the  
17 delta (Milliman et al., 1984). This relationship holds at the scale of the entire Holocene with  
18 roughly half of sediment discharge by the river contributing to the aggradation of the lower  
19 alluvial plain and subaerial delta and the other half contributing to the progradation of both the  
20 subaerial and subaqueous delta (Clift and Giosan, 2013).  
21  
22

23  
24 Schumm et al. (2002) considers the modern Indus plain to be comprised of two inland alluvial  
25 fans, one focused north of Sukkur and the other near Sehwan, with avulsions occurring near the  
26 apex of these fans. Based on higher resolution data, we see the floodplain more as a series of  
27 prograding and overlapping sediment fans or deposits (Figs. 2A, 2B, 3A) that reflect the  
28 movement of the historical Indus River (cf. Fig. 1). Schumm et al. (2002) regards the avulsions to  
29 be controlled by tectonics because avulsions appeared to have occurred repeatedly at the same  
30 location. The area containing Jacobabad- Khaipur lies close to the frontal folds of the Sulaiman  
31 lobe (Szeliga et al., 2010) and hence is influenced by incipient local fold-and thrust tectonics. The  
32 area immediately east of Karachi lies near an east-verging fold and thrust belt (Schelling, 1999;  
33 Kovach et al., 2010), whereas the eastern delta including the Rann of Kachchh is subject to  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58

60  
61  
62  
63  
64  
65

1  
2  
3  
4 footwall subsidence associated with reverse faulting of the Kachchh mainland and other faults  
5  
6 (Jorgensen et al 1993; Bendick et al., 2001; Biswas, 2005). That natural avulsions were triggered  
7  
8 by tectonic events is further evidenced by the fact that Mansurah (25.88°N, 68.78° E), the Arabic  
9  
10 capital of the Sindh province, was destroyed by an earthquake c. 980AD (Intensity  $\approx$ VIII),  
11  
12 resulting in a post-seismic avulsion of the river (Fig. 3 inset, Bilham and Lodi 2010). Since  
13  
14 natural levees have been observed in India to collapse during intensity VII shaking, it is  
15  
16 unnecessary to invoke co-seismic uplift as a requirement for upstream river avulsion (Bilham and  
17  
18 Lodi 2010). A similar possibly modest earthquake that occurred in 1668 in the historical province  
19  
20 of Nasirpur destroyed the town of Samawani (Fig. 3) and again initiated avulsion of the Indus  
21  
22 main channel (Bilham and Lodi 2010).  
23  
24  
25

26  
27 Levee breaching during significant flood events is thought to be directly responsible for other  
28  
29 historical river avulsions (Holmes, 1968). The relatively coarse sediment load favors formation of  
30  
31 new channels rather than reoccupation of older small channels, which silt up quickly to function  
32  
33 as secondary spillways (Holmes 1968).  
34  
35

36  
37 Figure 1 shows paleochannel locations recognized from planview fluvial architectural  
38  
39 elements, from visible satellite imagery (LANDSAT, SPOT, DigitalGlobe satellites), and  
40  
41 identified from their topographic expression (Syvitski et al., 2012) as reconstructed from the  
42  
43 SRTM topography (Fig. 2). Channel names (and their spelling) are from Holmes (1968), who  
44  
45 applied forensic historical analysis to determine when these channels would have been most  
46  
47 active. Holmes (1968) identified three channel patterns expressed within air photos (Fig. 1): circa  
48  
49 325 BC, 900 AD and 1600 AD. These dates represent generalized periods. Historical maps were  
50  
51 analyzed for their spatial geo-location error (Table 1), by digitally identifying towns on geo-  
52  
53 referenced maps and comparing them to modern city locations. Maps earlier than 1811 did not  
54  
55 have sufficient positioning detail to have their root-mean-square error determined. Few cities  
56  
57 lasted across multiple centuries, in part because Indus River avulsions commonly left river  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 settlements without water resources for drinking, agriculture, or transportation. [Note: Sindh  
5  
6 towns often changed their spelling and towns that were re-located sometimes kept their old name:  
7  
8 see supplementary spelling data].  
9

10  
11 Pinkerton (1811, see suppl. matl.) notes that the Indus River was navigable from the mouth to  
12  
13 the province of Lahore, 900 km upstream for ships of 200 tons. At that time the Indus River  
14  
15 system included an extensive set of natural overflow flood pathways across the Indus plain as  
16  
17 indicated by Lapie (1829, see suppl. matl.). An SDUK 1838 map shows the Indus flowing on  
18  
19 both sides of Bukkur, an island near Sukkur.. The same map indicates that the Indus was typically  
20  
21 500m wide, 12m deep, with a flow of 1.5 m/s (~4,500 to 9,000 m<sup>3</sup>/s) and rose 4m during flood  
22  
23 (i.e. ~12,000 to 16,000 m<sup>3</sup>/s) — values that are similar to those of today.  
24  
25

26  
27 The Western Nara River, a northern offshoot course of the main Indus, originated near  
28  
29 Kashmore (Fig. 1) in pre-historic time and later near Ghauspur (Panhwar, 1969). As the Indus  
30  
31 moved west, this distributary was 37 km north of Larkana by 1860 and only 15 km north by 1902,  
32  
33 when it was converted into a canal (Panhwar, 1969). Johnson (1861, see suppl. matl.) shows the  
34  
35 Eastern Nara River to be a viable secondary pathway of Indus water to the sea through a complex  
36  
37 of river channels. In 1859, the Eastern Nara was converted into a perennial canal (Panhwar,  
38  
39 1969). The Indus adopted its present course west of Hyderabad in 1758 when the Nasarpur  
40  
41 Course was deserted (Fig. 1) and discharge greatly decreased down the Eastern Nara (Fig. 1). The  
42  
43 Fuleti River, a significant discharge branch to the west of Hyderabad through the first half of the  
44  
45 19<sup>th</sup> century (SDUK 1933; Johnston 1861, see suppl. matl.), became a spillway and occupied the  
46  
47 channel of the former Ren River (Fig. 1).  
48  
49  
50

51  
52 Using aerial photography covering the region, Holmes (1968) recognized 1) meander deposits  
53  
54 formed by Holocene trunk river (e.g. pointbar deposits, deserted channels, and abandoned oxbow  
55  
56 lakes), and floodplain cover deposits, formed by vertical accretion of fine sediments in slow-  
57  
58 moving floodwaters of the basins. Cover deposits are widespread along the flanking zone from  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Jacobabad to Manchar Lake, in the southeast around Mirpur Khas and Umarkot, and in the delta  
5  
6 (Holmes 1968). The historical Indus River sent off distributaries and small seasonal spillway  
7  
8 channels towards its flanks and across the delta. Such smaller-scale channels are characterized by  
9  
10 levees rather than by river bars and meander scrolls. Levees of the Ghar and Western Nara (Fig.  
11  
12 1) are ~3 m high due to periodic overspill of their banks and define these 3 km-wide  
13  
14 paleochannels.  
15  
16

17  
18 Narrower channels and shorter wavelength meanders define former courses of the Indus: the  
19  
20 Khairpur at between 4km and 8km; Shahdapur at 5km; and the Warah at 6km (Fig. 1). The  
21  
22 modern Indus is wider with larger but fewer meanders (~14km wavelength). Sinuosity of the  
23  
24 paleo-Indus channels (Figs. 1 and 2) had a range from: 1) Badahri: 1.51, 2) Warah: 1.55, 3)  
25  
26 Kandhkot: 1.65; 4) Puran: 1.81, 5) Shahdadkot: 1.99, 6) Eastern Nara: 2.05, 7) Khairpur: 2.33,  
27  
28 and 8) Shahdadpur: 2.51. The modern Indus has sinuosity values ranging from 1.1 to 2.0 with a  
29  
30 mean value of 1.8 (see discussion below). Paleochannels therefore had similar or sometimes  
31  
32 greater sinuosity.  
33  
34

35  
36 The visible record of paleochannels represents only the last ~1000 years. The remotely sensed  
37  
38 topography of Figure 2 perhaps captures some of the longer record of river avulsion and  
39  
40 floodplain development and demonstrates how the floodplain aggrades through major avulsions  
41  
42 of the trunk Indus. The large channel belt switches leaving behind 1 to 3 m of super-elevated  
43  
44 channel belt deposits that shed crevasse-splay fingers and fans interweaving with cover deposits  
45  
46 to their sides (Figs. 2-5). An interesting feature of the imaged floodplain topography is its fan-like  
47  
48 appearance (Figs. 2, 5). When viewed along valley profiles (Fig. 3), these fan-like waves have a  
49  
50 first order wavelength of 29 km, upon which is superimposed a second order set of waveforms  
51  
52 with wavelength of ~3.6 km. We suggest that the first order waveform reflect the avulsion  
53  
54 frequency of the main Indus River (on the order of several centuries). Major avulsions shift the  
55  
56 loci of floodplain deposition suddenly, leaving behind these first-order super-elevated fan lobes  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 (see Fig. 2B). Whereas the second-order scale features perhaps relate to decadal occurrence of  
5  
6 floods that build up intermingled crevasse deposits around the larger paleochannel features (Fig.  
7  
8 5). The width and depth of the modern Indus and other paleochannels are well demonstrated in  
9  
10 both strike sections (Fig. 4) and plan view (Fig. 5). [Note: the February 2000 SRTM shuttle  
11  
12 topographic survey was collected at a time when much of the Indus was a dry bed river].  
13  
14 Radiocarbon-dated fluvial deposits of old channel belts in lower Sindh indicate that aggradation  
15  
16 on the megaridge was minimal during the late Holocene. This relative stability of the late  
17  
18 Holocene landscape suggests that the abandoned Khaipur and maybe the Western Nara courses  
19  
20 are likely older than ~2700 years and secondary in importance in historical times (Giosan et al.  
21  
22 2012).  
23  
24

25  
26  
27 The complex processes occurring along the Holocene Indus must, as well, have occurred in the  
28  
29 context of environmental and climate variability. Pollen studies from a core recovered from the  
30  
31 Arabian Sea off the Makran Coast (24° 50'N, 65° 55'E; 695 m depth) show an end of more  
32  
33 humid conditions, linked to a weakening of the monsoon, between 4700 and 4200 BP (Ivory and  
34  
35 Lézine, 2009). From tree ring analysis, Ahmed and Cook (2011) conclude, as regards to current  
36  
37 water supply along the Indus: “Perhaps the most worrying feature in the streamflow  
38  
39 reconstruction is the occurrence of a pronounced and prolonged 112 year low-flow period from  
40  
41 AD 1572 to 1683 (median: 3,404 m<sup>3</sup>/s) and a shorter but much drier 27 year period from AD  
42  
43 1637 to 1663 (median: 3,292 m<sup>3</sup>/s). The former is ~7% below and the latter ~10% below the  
44  
45 median of the observed discharge record”. These initial inferences and numerical estimates form  
46  
47 a useful Holocene context to the larger changes of the Anthropocene; they constitute the “natural”  
48  
49 environmental variability on top of which the human-driven changes are occurring.  
50  
51  
52  
53

### 54 ***The Anthropocene River***

55  
56  
57 The Indus River presently feeds the world’s largest irrigation system (Fahlbusch et al. 2004). The  
58  
59 Pakistan irrigation system is comprised of 3 major storage reservoirs, 19 barrages, and 43 major  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 canals with a total conveyance length of 57,000 km. There are 89,000 watercourses with a  
5  
6 running length of more than 1.65 million km (Inman et al. 2007). Major modifications to natural  
7  
8 flows started as early as 1762 when the Phuram River at Mora was dammed as an act of  
9  
10 aggression by Ghulam Shah Kalora to destroy crop production in the Rann of Kachchh. The  
11  
12 Mora Bund apparently still permitted seasonal flow of the river and additional dams were  
13  
14 constructed downstream until in 1783, when the Aly Bundar dam successfully closed the  
15  
16 southward egress of the eastern Nara to the sea at Lakput. River traffic between 1762 and 1826  
17  
18 was undertaken by barges between the dams until a flood destroyed all the dams in 1826,  
19  
20 including the natural Allah Bund (a reverse fault scarp ridge) associated with the 1819 earthquake  
21  
22 (Burnes, 1828). Development of the modern system began in 1859 when the Eastern Nara Canal,  
23  
24 from Sukkur to the Eastern Nara River, changed the Eastern Nara from an overflow channel into  
25  
26 a perennial branch of the Indus.  
27  
28  
29

30  
31 The human footprint includes:  
32

- 33  
34 1. Construction of artificial levees to protect agricultural lands from inundation by  
35  
36 floodwaters of the Indus, which started in 1869 near Sukkur (Asianics Agro-Dev 2000). By  
37  
38 the time the Sukkur Barrage was constructed in 1932, the eastern bank included a complete  
39  
40 line of bunds from the Sindh/Punjab border to Sehwan, and continuing 1500 km all the way  
41  
42 to the Indus delta (Asianics Agro-Dev 2000). With the completion of the Kotri Barrage in  
43  
44 1955, associated flood bunds constricted the active Indus River to a floodplain only 7 to 15  
45  
46 km wide. The Indus fluvio-deltaic system was harnessed and constricted to a single channel.  
47  
48  
49
- 50  
51 2. Construction of the barrages and associated irrigation canals has led to a systematic  
52  
53 abstraction of water from the Indus River. Twenty-three barrages offer a diversion capacity  
54  
55 of 69,500 m<sup>3</sup>/s (Asianics Agro-Dev 2000). The 1932 Sukkur Barrage (Fig. 1) can divert  
56  
57 1642 m<sup>3</sup>/s (Inman et al. 2007). The 1955 Kotri Barrage (Fig. 1) increased diversion  
58  
59 capacity by 992 m<sup>3</sup>/s. The 1962 Gudu Barrage increased capacity of 1,281 m<sup>3</sup>/s (Inman et  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 al. 2007). Canals often follow former river courses or floodways.

- 5  
6  
7 3. Storage capacity of all dams in the Indus basin is more than 23 km<sup>3</sup>; the Warsak Dam and  
8  
9 Mangla dam, completed in 1960 and 1967 respectively, have a combined storage of ~10  
10  
11 km<sup>3</sup>; the 1974 Tarbela dam adds another ~14 km<sup>3</sup> (ICOLD, 1998).  
12  
13  
14 4. The average pre-Anthropocene annual inflow to the Indus River system was ~220 km<sup>3</sup>/y,  
15  
16 but 42 km<sup>3</sup>/y of the upper Indus eastern rivers is now diverted to India and the total average  
17  
18 abstraction of Indus water for irrigation and other uses is 129 km<sup>3</sup>/y (Asianics Agro-Dev  
19  
20 2000). Of the remaining water, 96.8% is used for agricultural purposes (in 2002), 1.6% is  
21  
22 for domestic use and another 1.6% for industrial use (Inman et al. 2007). Groundwater  
23  
24 withdrawal for agriculture is estimated at 6.2 km<sup>3</sup>/y (Inman et al. 2007).  
25  
26

27 The Indus of the Anthropocene is a completely manipulated hydrological system (Syvitski and  
28  
29 Brakenridge, 2013), constrained by levees that have greatly changed both form and function of  
30  
31 the river when compared with earlier channel belts. To examine the effects of these changes in  
32  
33 more detail, we consider the evolution of river channel sinuosity and lateral migration rates.  
34

35  
36 Sinuosity is the ratio of thalweg length to river valley length, using appropriate length scales  
37  
38 (Knighton 1998). Migration rates are determined from changes in thalweg position between any  
39  
40 two time-intervals, for example every 2 km along the Indus River. We use the years 1944  
41  
42 (USACE 1944 maps; with a geolocation RMS error 196 m, Table 1), 2000 (SRTM, RMS error 55  
43  
44 m, Table 1) and 2010 pre and post-flood data (MODIS, RMS error 50 m). Figure 1 provides the  
45  
46 1944, 2000 and post-flood 2010 Indus thalweg. The 1944 data are from Survey of India Maps  
47  
48 updated with aerial photography by Army Map Service (USACE 1944 & suppl. matl.). The 1944  
49  
50 maps predate a 70% reduction of water discharge and an 80% reduction of its sediment load that  
51  
52 followed a major increment in the emplacement of barrages and dams Milliman et al. 1984). We  
53  
54 contrast these migration rates so determined, with those resulting from the 2010 flood on the  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Indus River when  $\sim 40,000 \text{ km}^2$  of floodplain was inundated and 20 million Pakistani citizens  
5  
6 were displaced, accompanied by 2000 fatalities (Syvitski and Brakenridge, 2013).  
7  
8

9 The fluvial reach of the Indus River below Sukkur exhibited a sinuosity of 1.63 in 1944.  
10 Sinuosity was 1.81 in 2000 and 1.82 by 2010 (pre-flood). After the 2010 river flood, sinuosity  
11 decreased to 1.71 in just two months. Pakistan has experienced severe floods in 1950, 1956, 1957,  
12 1973, 1976, 1978, 1988, 1992 and 2010 (Hashmi 2012). The lateral migration between 1944 and  
13 2000 was  $1.95 \pm 0.2 \text{ km}$  on average (Fig. 6), a rate of 36 m/y, but only 14 m/y between the 2000  
14 and 2010 pre-flood imagery. Remarkably during the 2010 flood, the lateral migration rate  
15 averaged 339 m in just 52 days, or 6.5 m/d. This rate suggests that the action of decadal flood  
16 events is the dominant control on the long-term migration and reworking of a channel belt.  
17  
18

19 Sinuosity in the portion of the delta plain river influenced by tidal pumping (downstream of  
20 Thatta, Fig. 1) was 1.48 in 1944, 1.65 in 2000 (an increase of 35%), 1.75 in 2010 pre-flood and  
21 1.70 in post-flood 2010. Similar to the fluvial-only reach, the tidal influenced portion of the  
22 river's sinuosity decreased by 7%. Lateral migration rates between 1944 and 2000 were 30 m/y,  
23 20% smaller than in the fluvial reach (Fig. 5A). The migration rate, between 2000 and 2010 (pre-  
24 flood), was 5 m/y. During the 2 months of the 2010 flood, the tide-influenced Indus channel  
25 migrated 198.5 m, or 4 m/d. A major upstream avulsion, north of Sukkur, greatly reduced the  
26 flow discharge in the main trunk river during the 2010 flood, so that the Indus only carried 43%  
27 of its upstream maximum discharge (Syvitski and Brakenridge, 2013).  
28  
29

## 30 **The Indus Delta**

### 31 *The Pre-1869 or More Natural Delta State*

32 The more natural Indus Delta is characterized by high river discharge, moderate tides and high  
33 wave energy conditions (Giosan et al. 2006). The delta shoreline advanced southwards and  
34 westwards at rates of between 4 and 30 m/year given the fluvial sediment delivery of over 400  
35

63  
64  
65

1  
2  
3  
4 Mt/y (Kazmi 1984); Milliman et al. (1984) suggest a pristine delivery rate between 270 and 600  
5  
6 Mt/y. The delta occupied an area of about 17,000 km<sup>2</sup> consisting of ~16 major tidal channels,  
7  
8 mudflats and mangrove forest. The Indus River experienced tides inland as far as Thatta ~160 km  
9  
10 upstream (Eisma 1998). The slope of the Indus River decreases by 50% (from 0.00008 to  
11  
12 0.00004) across the lower delta plain (Fig. 2).  
13  
14

15  
16 Drainage patterns of the Indus Delta are sensitive to seismic activity, especially in the  
17  
18 Kachchh portion of the Eastern delta. The western Rann has subsided in historical times, and  
19  
20 tributaries of the Indus have dried up as the river distributaries changed their courses (Bilham,  
21  
22 1998; Iyengar et al, 1999; Thakkar et al., 2013). The 1819 Rann of Kachchh earthquake (Fig. 3)  
23  
24 that caused more than 1500 deaths, had an estimated magnitude  $7.7 < M_w \leq 8.2$ , and was felt over a  
25  
26 large part of India. Earthquake-induced subsidence formed Sindri Lake (Burnes, 1828) evident  
27  
28 on all 19<sup>th</sup> century maps (see Suppl. matl.) and identifiable on recent imagery, and uplifted land  
29  
30 approximately 80 km long, 6 km wide and  $\leq 6$  m high, which dammed the Puram River (Bilham  
31  
32 et al. 2007). Prolonged aftershock activity continued for at least 50 years, including an estimated  
33  
34 magnitude of 6.5 in 1846 (Bilham 1998). The 1819 earthquake also resulted in minor uplift north  
35  
36 of Lukpat and subsidence in the delta west of the Kachchh mainland (Thakar et al 2012), and  
37  
38 blockage of the important delta port of Shahbunder (Hughes, 1876).  
39  
40  
41  
42

43  
44 In more pristine conditions, the Indus delta prograded tremendously, and Holmes (1968)  
45  
46 reconstructed the active coastline at 325BC almost 100km inland from the current coast (an  
47  
48 averaged rate of ~44 m/y). Progradation in the 19th century was over 200m/y near the active river  
49  
50 mouth (Giosan et al., 2006). Figure 7 provides snapshots of the geolocated distributary channels  
51  
52 of the Indus through this historical period. Consistently, these historical maps show a main  
53  
54 channel coinciding with multiple other distributary channels in the delta plain. During the early  
55  
56 map period between 1768 and 1811, the main Indus delta channel was along the western portion  
57  
58 of the delta. The Jefferys (1768) map shows the main Indus channel following the paleo-Kalri  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Branch, and a second major channel flowing along what is now the modern Indus southeast of  
5 Tatta (Thatta) and then along what is the paleo-Sattah branch (labeled Nala Sunkra; see suppl.  
6  
7  
8  
9 matl.).

10  
11 By 1804 (Rennell 1804; see suppl. matl.), the Nasirpur course (called the Dimtadee River on the  
12  
13  
14 map) flowed immediately to the north of the town of Nasirpur. The map of Arrowsmith (1804;  
15  
16 see suppl. matl.) notes that the Indus flood season over the delta was in April, May and June, two  
17  
18 months earlier than today, possibly indicating a greater contribution from the Himalaya.  
19  
20 Pinkerton (1811; see suppl. matl.) states that the Indus River is navigable for 900km upstream.  
21  
22 Steamships continued to ply the river as a cargo transport to Attock until replaced by railways in  
23  
24 1862 (Aitkin, 1907). The Baghar channel (Fig. 1) began to silt up in circa 1819. The Indus River  
25  
26 then forged its main channel down its former Sattah Branch, but turned west, reaching the sea via  
27  
28 the Ochito Branch (Fig. 1; Holmes 1968). Through the period 1830 - 1865 (SDUK 1833,  
29  
30 Johnston 1861; see suppl. matl.) the main Indus delta channel was located along the modern  
31  
32 Indus course, and numerous distributary channels were maintained both to the west and to the  
33  
34 southeast (Fig. 7). On an 1833 map (SDUK 1833; see suppl. matl.) the tide is stated as reaching  
35  
36 inland 111 km. By 1870-1910 (Letts 1883; see suppl. matl.), the main Indus had shifted further  
37  
38 south and east while still maintaining flow to the western distributary channels (Fig. 7; also see  
39  
40 Johnston and Johnston 1897 in the suppl. matl.). By 1922 (Bartholomew, 1922 suppl. matl. and  
41  
42 Fig. 7), the Ochito River channel was the main branch, but this had largely been abandoned by  
43  
44  
45 1944 (Fig. 7).  
46  
47  
48  
49

#### 50 *The post 1869 or Anthropocene Delta*

51  
52 The Indus channel is reduced to a single thread in its deltaplain, and the number of delta  
53  
54 distributary channels has decreased during the 19<sup>th</sup> century, from ~16 to 1 (Table 1, Fig. 6). The  
55  
56 modern delta does not receive much fluvial water or sediment. There were zero no-flow days  
57  
58 prior to the Kotri Barrage construction in 1955. After construction (c. 1975), up to 250 no-flow  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 days per year occur. The average annual water and sediment discharges during 1931–1954 were  
5  
6 107 km<sup>3</sup> and 193 Mt, respectively. During the 1993 to 2003 period these rates dropped an order-  
7  
8 of-magnitude to 10 km<sup>3</sup> and 13 Mt (Inam et al, 2007). The Indus discharge downstream of the  
9  
10 Kotri Barrage is usually limited to only 2 months: August–September, with the sea now intruding  
11  
12 the delta up to 225 km (Inam et al, 2007).  
13  
14

15  
16 Abandoned Indus delta channels have been tidally reworked all along the coast (Figs. 8, 9).  
17  
18 We mapped this evolution of delta channels using high-resolution imagery: 1) the 1944  
19  
20 topographic maps (USACE 1944; RMS location error  $\pm$  196m), 2) the 2000 SRTM/SWDB  
21  
22 database (see suppl. matl.; RMS error  $\pm$  55m), and 3) LANDSAT imagery from 1978, 1989, 1990,  
23  
24 1991, 2000 (RMS location error between  $\pm$  32m and 196m). Imagery was selected to be  
25  
26 representative of being part of the same astronomic tidal stage. By differencing the images we  
27  
28 determined areas that had experienced sediment deposition or erosion on the tidal flats and new  
29  
30 tidal channel formation (Fig. 9).  
31  
32

33  
34 In the western Zone 1 (Fig. 8), the deltaic coast nearest Karachi, the 1944 tidal creeks show  
35  
36 only minor amount of channel migration, a slight increase in tidal channel density in the outer  
37  
38 flats, an increase in tidal channel density in the inner flats, and little to no increase in tidal  
39  
40 inundation limits. Zone 1 had a net land loss of 148 km<sup>2</sup> incorporating areas of both erosion and  
41  
42 deposition (Table 2, Fig. 8). Imagery in between 1944 and 2000 indicates that the shoreline saw  
43  
44 episodic gains and losses. Giosan et al (2006) also noted that the shoreline in Zone 1 was  
45  
46 relatively stable since 1954, but experienced progradation rates of 3 to 13 m/y between 1855 and  
47  
48 1954.  
49  
50

51  
52 The west-central part of the delta (Zone 2 in Fig. 8) that includes the minor of two river  
53  
54 mouths still functioning in 1944, shows larger changes: a >10 km increase in tidal inundation  
55  
56 limits, the development of a dense tidal creek network including the landward extension of tidal  
57  
58 channels, and shorelines that have both advanced and retreated. Zone 2 had a net loss of 130 km<sup>2</sup>  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 (Table 2, Fig. 8). The Ochito distributary channel had been largely filled in with sediment since  
5  
6 1944.  
7

8  
9 In the south-central part of the delta (Zone 3 in Fig. 8) is the zone where 149 km<sup>2</sup> of new land  
10 area is balanced with 181 km<sup>2</sup> of tidal channel development (Table 2). The Mutni distributary  
11 channel, the main river mouth in 1944, and its associated tidal creeks, were filled in with  
12 sediment by 2000. Before the Mutni had avulsed to the present Indus River mouth, much  
13 sediment was deposited and the shoreline had extended seaward by more than 10 km (Figs. 8, 9).  
14 Large tidal channels were eroded into the tidal flats and tidal inundation was extended landward.  
15 We suspect that eroded tidal flat sediment contributed to the shoreline progradation in zone 3 of  
16 150 m/y. Most of the progradation was prior to the 1975, in agreement with Giosan et al (2006).  
17  
18  
19  
20  
21  
22  
23  
24  
25  
26

27 The eastern Indus delta (Zone 4 in Fig. 8) experienced the most profound changes. Almost  
28 500 km<sup>2</sup> of these tidal flats were eroded into deep and broad (2-3 km wide) tidal channels,  
29 balanced by < 100 km<sup>2</sup> of sediment deposited in older tidal channels (Fig. 8). Tidal inundation is  
30 most severe in zone 4 (Fig. 8).  
31  
32  
33  
34  
35  
36

37 In summary, during the 56-yr study interval parts of the Indus Delta lost land at a rate of 18.6  
38 km<sup>2</sup>/y, while other parts gained in area by 5.9 km<sup>2</sup>/y, mostly in the first half of this period. During  
39 this time a stunning 25% of the delta has been reworked; 21% of the 1944 Indus delta was eroded,  
40 and 7% of the delta plain was formed (Table 2). To approximate these area loss or gain rates, to  
41 sediment mass we use 2 m for the average depth of tidal channels (see section C3 in Fig. 4). The  
42 erosion rate is then ~69 Mt/y, whereas the deposition rate is ~22 Mt/y, corresponding to a mean  
43 mass net loss of ~47 Mt/y. For the 72 y period 1931-2003, Inam et al. (2007) cite Pakistan  
44 Irrigation Department data indicating that 7.2 Gt of sediment was delivered to the Indus Delta at a  
45 mean rate of 100.6 Mt/y. Therefore if the delivery of 100 Mt/y of river sediment results in a net  
46 land loss equivalent of 47 Mt/y, then the pre-Anthropocene flux estimate of 250 Mt/y (Milliman  
47 et al. 1984) would result in an active Indus delta able to both aggrade and prograde seaward. The  
48

1  
2  
3  
4 sediment budget remains qualitative, as it does not take into account subsidence across the delta,  
5  
6 for lack of quantitative data. Satellite analysis suggests that there is significant sedimentation  
7  
8 within the inner tidal flats of the Rann of Kachchh (Fig. 10), further complicating a full  
9  
10 quantitative assessment.  
11

12  
13 Although part of the Rann of Kachchh (Lake Sindri south of the Allah Bund) underwent >1  
14  
15 m of incremental tectonic subsidence in 1819 it is not known whether slow secular subsidence  
16  
17 occurs between earthquakes, either due to tectonic subsidence or sediment compaction. Tidal  
18  
19 energy has been focused towards the eastern margins of the delta, apparently responding to  
20  
21 changed hydraulic gradients or to the absence of sediments from the now inactive eastern  
22  
23 distributaries. Evidently the sediment supply to Lake Sindri in the past 200 years has been  
24  
25 insufficient to fill the tectonically induced basin since it remains a 20 x 30 km<sup>2</sup> basin, 1-2 m deep  
26  
27 (Fig. 10). In contrast, the tidal flats in the western part of the Indus delta appear to be more  
28  
29 stable, possibly protected from tidal and wave reworking of the shoreline by the absence of  
30  
31 tectonic subsidence or possibly due to the presence of slow uplift.  
32  
33  
34

35  
36 The effects of the transition to the Anthropocene delta due to its much-increased abstraction  
37  
38 of water upstream are pronounced and well documented: seawater intrusion, soil salinization,  
39  
40 deforestation of mangroves, reduced supply of surface- and ground-derived drinking water, low  
41  
42 irrigation flows, and greatly depleted fisheries. Shrimp production has decreased by 90% (Inam et  
43  
44 al, 2007). The delta's mangrove forest, which covered ~2500 km<sup>2</sup>, has been reduced by 60%  
45  
46 (Kamal 2004). The degraded mangrove ecosystem is virtually mono-specific, comparatively  
47  
48 stunted, with losses of about 2% per year (Asianics Agro-Dev. 2000). The increase in salinity  
49  
50 during periods of low flow, and from the effects of upstream irrigation, has reduced the suitability  
51  
52 of the delta for the cultivation of red rice, and for raising livestock. The herds of delta cattle,  
53  
54 sheep and goats that once roamed the lower delta have disappeared; only herds of camel are to be  
55  
56 found (Asianics Agro-Dev. 2000). The Anthropogenic Indus delta is hardly a true delta anymore,  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 it receives too little water and sediment from the fluvial system, and tidal processes have taken  
5  
6 control of the environment. In effect, it is a relict landform from pre-Anthropocene time.  
7  
8

## 9 **Discussion and Conclusions**

10  
11 The hinterland of the pristine Indus river and delta system contributed annually 270 – 600 Mt of  
12  
13 sediment towards its lowland floodplains and the ocean, creating a ~17,000 km<sup>2</sup> large delta over  
14  
15 the Holocene that prograded up to 200 m/y until a century ago. The upstream river switched  
16  
17 multiple times over the last 1000 years, occupying its entire 150 km-wide container valley. A  
18  
19 multitude of channel belts aggraded and built 3-4 m high, several-km-wide, super-elevated ridges  
20  
21 throughout the Indus plain. Detailed SRTM-InSAR topographic data highlight the positions of  
22  
23 these large-scale ribbons. We also detect the topographic footprint of smaller scale crevasse  
24  
25 splays and crevasse fingers shedding off the main channel. Some of these major river avulsions  
26  
27 accompanied moderate earthquakes, and it is possible that a future earthquake could force the entire  
28  
29 modern river system to abandon its current super-elevated course and reoccupy one of several lower  
30  
31 elevation paleo-courses. As a result, river water would be diverted to a new path many tens or  
32  
33 hundreds of km from its current channel, circumventing the extensive engineering works designed to  
34  
35 constrain its current channels (see sections X4 and X8 in Fig. 4).  
36  
37  
38

39  
40 This river system became noticeable dominated by human action from 1869 onwards, with the  
41  
42 systematic construction of continuous levees, which transformed the more natural drainage  
43  
44 network into the world's largest irrigation system and reduced the sediment flux towards the  
45  
46 Indus Delta to ~13 Mt/y. The engineering system harnessed the river into a narrow corridor of  
47  
48 just 15 km wide. It appears that the present-day channel belt is super-elevated (~8m) more than  
49  
50 paleochannel belts (3-4m). However, within this narrow floodplain corridor, the channel is still  
51  
52 dynamic. This study also observed that the meander wavelength of the modern Indus is some  
53  
54 200% to 300% larger than for those historical Indus channels still evident in present-day  
55  
56 landscape imagery. A positive change in meander wavelength is often associated with an  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 increase in discharge (Hicken 1995, Chapter 7). It is possible as suggested earlier, that the impact  
5  
6 of tight levees or bunds, is to both constrain and capture larger floodwaves along the modern  
7  
8 Indus (Syvitski and Brakenridge, 2013). The period before levee construction saw numerous  
9  
10 natural spillways that limited the flood discharge magnitude by releasing water into the dry desert.

11  
12  
13  
14 This study reveals that the river sinuosity changed from 1.63 below Sukkur in 1944 to 1.82 in  
15  
16 2010 (pre-flood conditions). After the 2010 river flood, the sinuosity decreased to 1.71. The  
17  
18 centerline of the main channel migrated lateral  $1.95 \pm 0.2$  km over the same period (or 36 m/y)  
19  
20 with an astonishing average of 339 m migration in just 52 days comparing pre and post flooding  
21  
22 main channel centerline positions. This data suggests that the 66 year channel migration total  
23  
24 perhaps occurred largely during only 8 flood events: peak events occurred in 1950, 1956, 1957,  
25  
26 1973, 1976, 1978, 1988, 1992 and 2010 (Hashmi 2012). These migration rates occur despite the  
27  
28 extensive system of artificial levees, and the erosion poses acute danger to people, livestock and  
29  
30 infrastructure during the floods, and mandates considerable maintenance and repair after floods.  
31  
32 We speculate that this damage will only exacerbate with a continued aggradation in the main  
33  
34 channel, much like the repetitive cycle of the historical Yellow River levee breaches and floods  
35  
36 (Chen et al., 2012).  
37  
38  
39  
40

41 In summary, the anthropogenic impacts upstream and tectonic controls downstream have led in a  
42  
43 short time to the following morphological changes to the delta:  
44

- 45 1) The number of distributary channels reduced from 17 in 1861 to just 1 in 2000.
- 46  
47 2) A change has occurred from a fluvial-dominated delta system to a more tidally controlled  
48  
49 system, with reworking of the abandoned delta channels along the coast. The main portion of  
50  
51 the delta is now a relict landform.
- 52  
53 3) Tectonic -induced subsidence at the eastern part of the delta and stable conditions to possible  
54  
55 uplift in the west have resulted in accelerated coastal erosion at the Rann of Kachchh area  
56  
57 (eastern part of the delta).  
58  
59  
60  
61  
62  
63  
64  
65

- 1  
2  
3  
4 4) Since 1944, the delta has lost 12.7 km<sup>2</sup>/y of land; 25% of the delta has been turned over, 21%  
5  
6 of the delta was eroded and 7% of new land was added. This equals an annual sediment loss  
7  
8 of ~47Mt, assuming 2m depth average tidal channels.  
9

10 We speculate that the deterioration of the Indus delta from its previous state was initiated and is  
11  
12 maintained by human-caused perturbations; mainly, the upstream use of water and the trapping of  
13  
14 the associated sediment flux. According to our findings, self-regulating processes have largely not  
15  
16 buffered these changes; instead, some have indeed initiated self-enhancing mechanisms (e.g.,  
17  
18 changes in river form in response to floods). It is unlikely that the river-delta system, now  
19  
20 dominated by tidal processes, could be converted back to its pre-Anthropocene state. Yet the  
21  
22 present system exhibits trends that, if left unmitigated, will affect sustained habitability by the  
23  
24 human population.

Figure 1. General map of the Indus floodplain and delta; towns/cities used in text are identified with geographic features and the salt (green) line of the Indus Delta. The 2000 position of the Indus River (dark blue) is from SRTM/SWBD data, the 1944-Indus (purple) is from USACE data, and the 2010 post flood image (black) is from Landsat 5 imagery. Paleo-Indus channels are from satellite imagery; their names and age are from Holmes 1968. Delta and floodplain boxes represent SRTM data locations of Figures 5A and 5B.

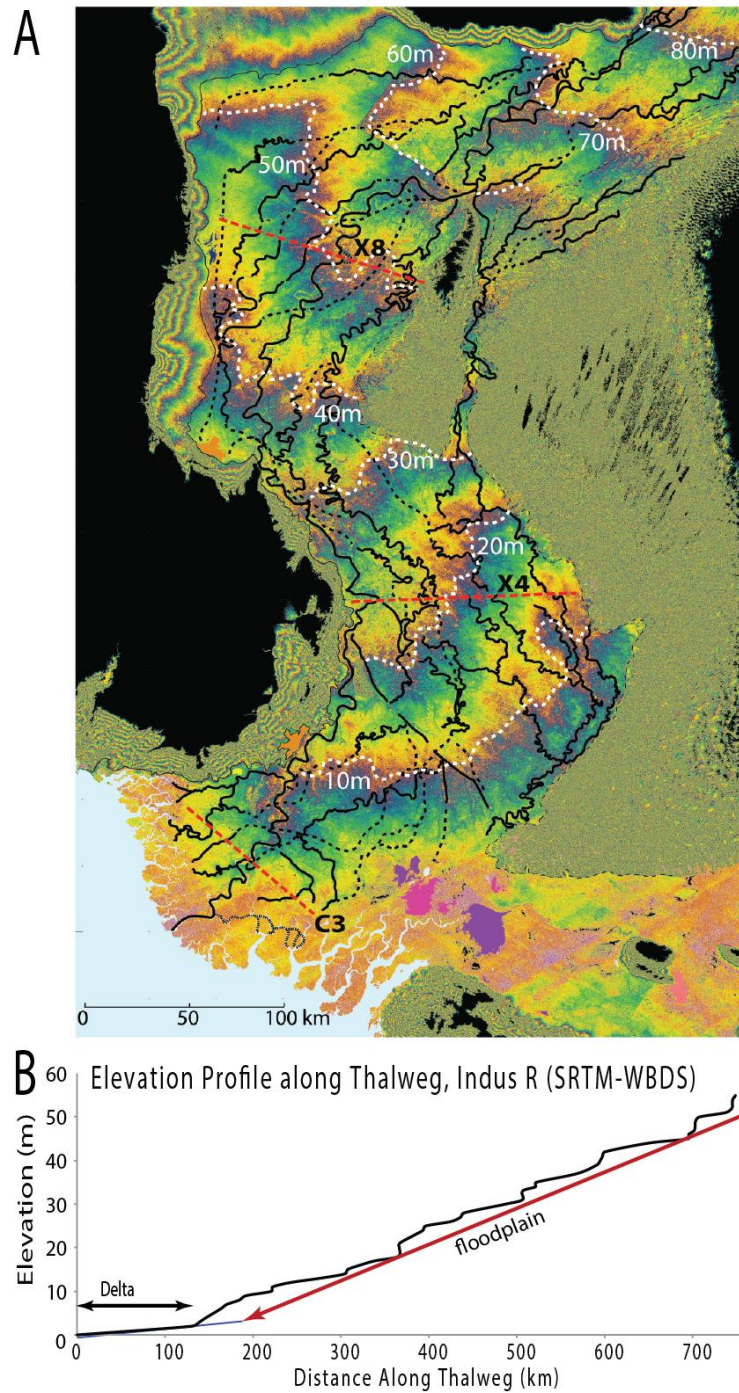

Figure 2. A) Floodplain imaged with SRTM C-band InSAR — colors change every 1 m of vertical elevation and cycle every 10 m; black elevations are >100 m. Superimposed on the digital elevation model are the modern (2000) and paleo Indus river channels as differentiated in Figure 1. Also superimposed are the generalized 10m elevation contours as a visual aid. Figure 4 profile locations are in dashed red and labeled. B) Elevation profile of the Indus thalweg using SRTM-WBDS data. Note the very different slopes between the Delta portion and the Indus floodplain portion. Also note the sediment waves (steps) seen in the river profile.

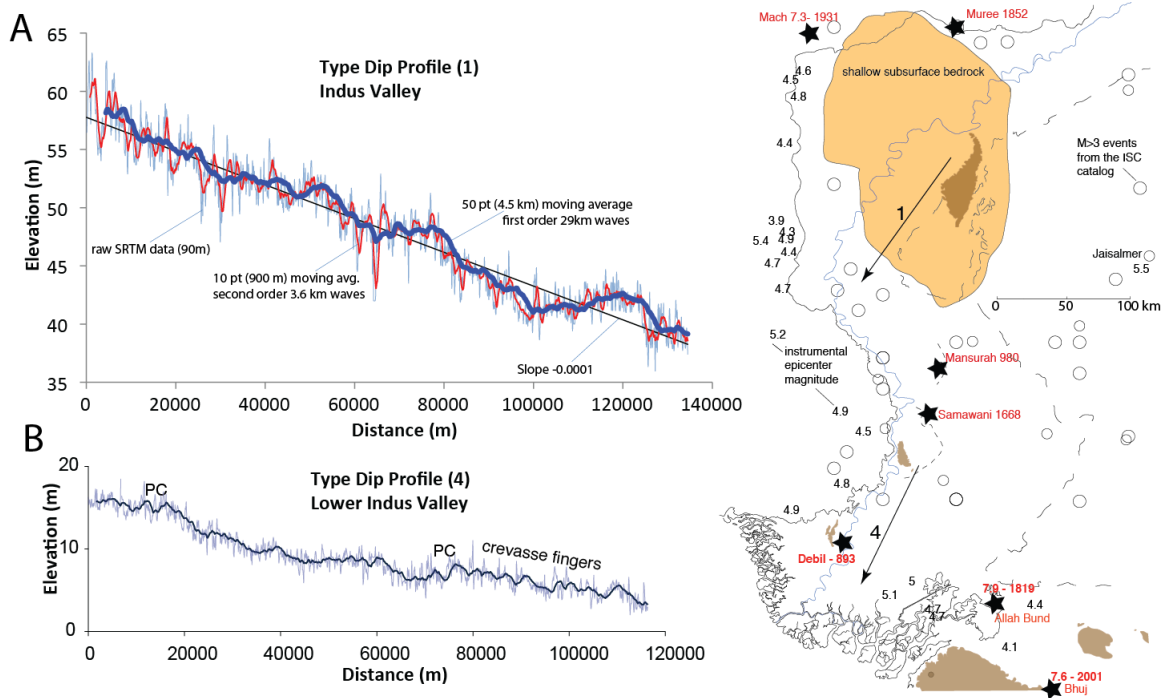

Figure 3. DEM-based dip profiles generated from SRTM data (see Fig. 2) showing raw 90 m profiles, 50 point (4.5 km) moving average profiles showing first order 29 km sediment waves, and 10 point (900 m) moving average profiles showing second order 3.6 km waves. The raw SRTM 90m signature is itself based on 30m data averaged by NGA around the mid-pixel. This raw signature shows 3 – 8 m vertical fluctuations with a horizontal wavelength of 1.8 km off of the linear down-valley slope of 1:10000 ( $5.7 \times 10^{-3}$  degrees). Also identified on the profiles are the crevasse fingers seen in Fig. 2 and the paleo-channels (PC) identified in Fig. 1 and 2. The inset map after Bilham *et al.*, 2010, shows the zone of shallow subsurface bedrock centered at Sukkur, along with instrumental seismic activity to 2001 denoted by numerical magnitudes, less accurate  $M < 3$  epicenters by open circle. Damaging earthquakes both historical (893 -Kovach *et al.*, 2010, c. 980, 1668, & 1819 for which magnitudes are inferred or unavailable) and instrumental (1930-2001 indicated by stars with magnitudes).

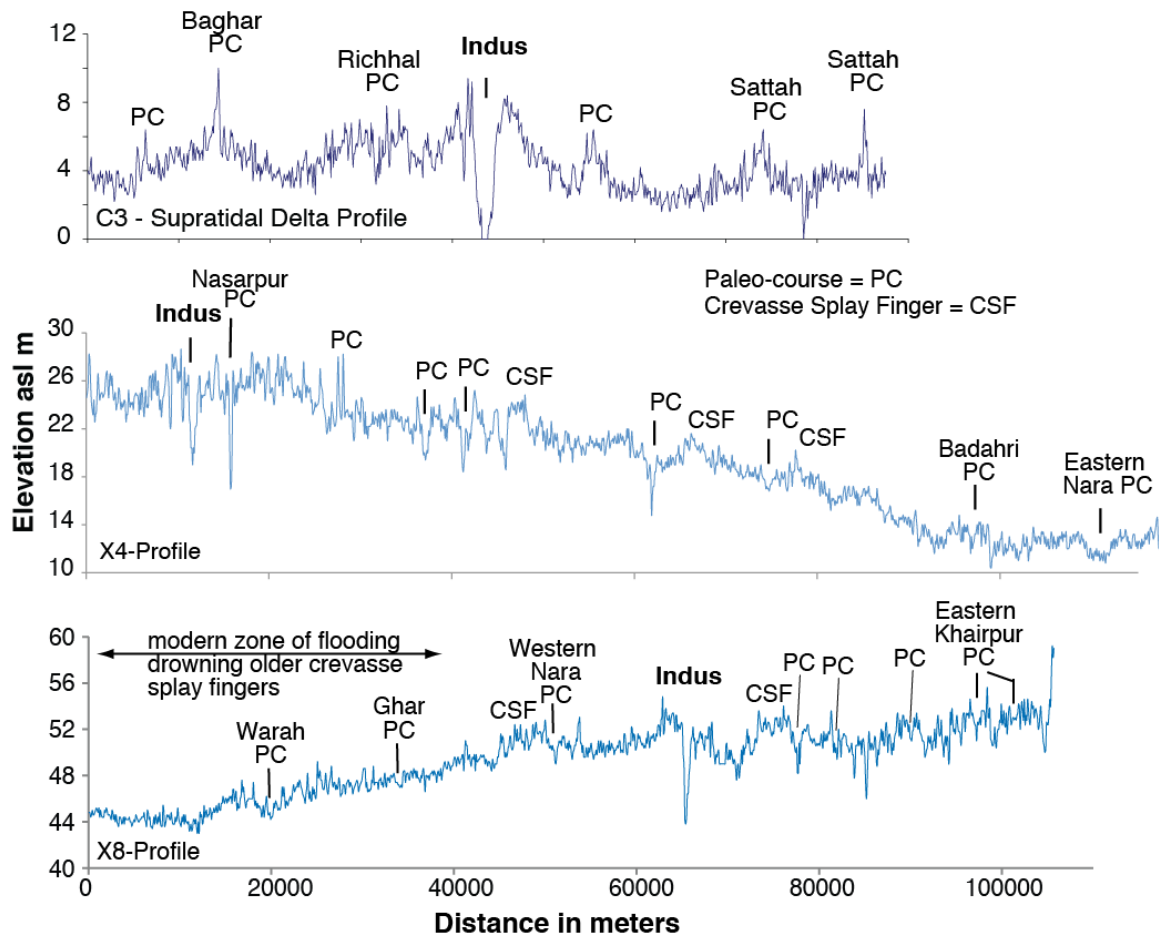

Figure 4. Cross-valley strike profiles (Fig. 2 for map location) of elevation across the paleo Indus floodplain are based on 90m SRTM DEM. The inset shows paleo and modern channels, the modern floodplain and the strike sections). Profiles are comprised of the average of five 90m-spaced parallel profiles to eliminate spurious roughness features. At section C3, the Indus is well expressed as an 8 m deep channel, and other paleo channels are super-elevated above the surrounding floodplain similar to crevasse splays. For sections further up-valley, paleo channels are cut into the floodplain between 1 and 4 m. The Nasarpur Channel (e.g. X4) and the Shahdadpur Channel are the same relief and dimensions as the modern Indus. Other paleo channels such as the Eastern Khairpur (e.g. X8), and Eastern Nara (e.g. X4) are smaller, and many others are much smaller.

Figure 5: SRTM images of the A) Indus Delta, <13m above sea level, and B) the Indus or Sindh floodplain between 39 and 55m above sea level (see Fig. 1 for locations). Colors change every m; color pattern repeats every 10 m; light blue is mean sea level. A) 1-Kalri paleo-branch; 2-Malaki paleo-branch; 3-Baghar paleo-branch; 4-Richhal paleo-branch; 5-Orchito paleo-branch; 6-Sattach paleo-branch; 7-Sir paleo-branch; 8-Gongro paleo-branch; 9-relatively recent splay off of the Indus (see Figure 5C). B) 10-paleo Dadu channel; 11-paleo Khairpur channel; 12-paleo Western Nara channel; 13-paleo Ghar channel; 14-paleo Jacobabad or Shahdadkot channel partially buried in flood deposits of paleo Lake Manchur); 15-paleo Warah channel; 16-crevasse splay fingers off of the paleo Ghar channel now occupied by irrigation canals. C) 2007 Digital Globe image (inverted for contrast) of an elongated Indus crevasse splay finger (CSF) that has become eroded from tidal action (see oval). D) 2008 Digital Globe image of a paleo crevasse-splay levee likely from the paleo-Gongro. A recent irrigation canal has been cut into the levee deposit. The inset shows erosional channels cutting across the splay levee from canal floodwaters.

Accepted Manuscript

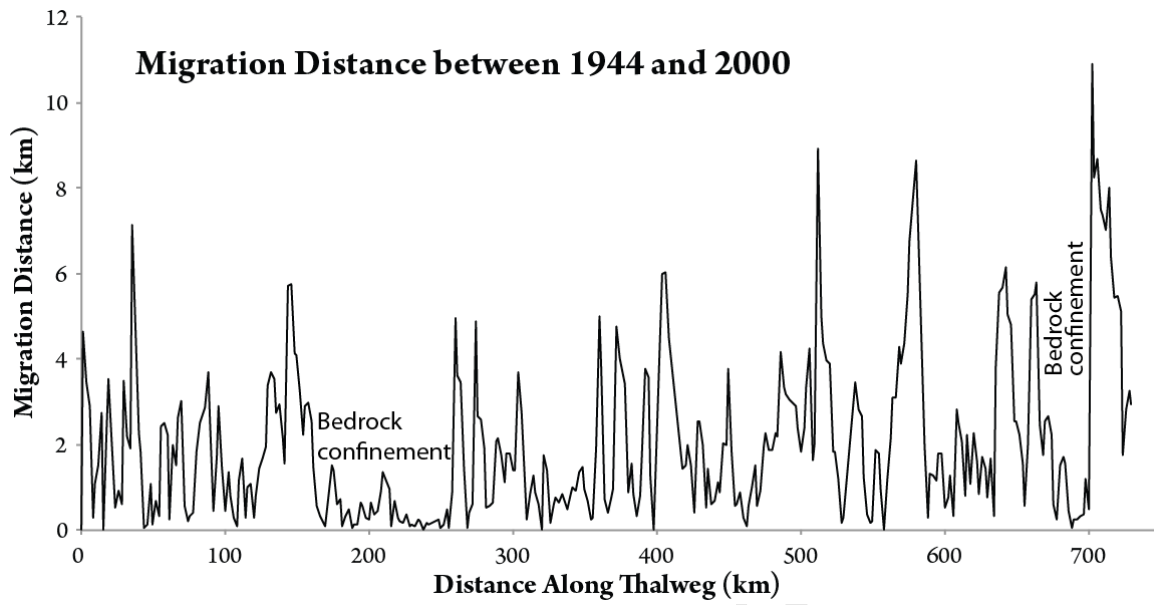

Figure 7. Distance between the position of the 1944 Indus Channel (USACE 1944) and the 2000 channel position (90 m-resolution SRTM, see Table 1). Large areas of limited migration are due to channel pinning by bedrock valley confinement.

Figure 6. Geo-located distributary channels of the Indus from 1800 to 1944, using historical maps (cf. Table 1).

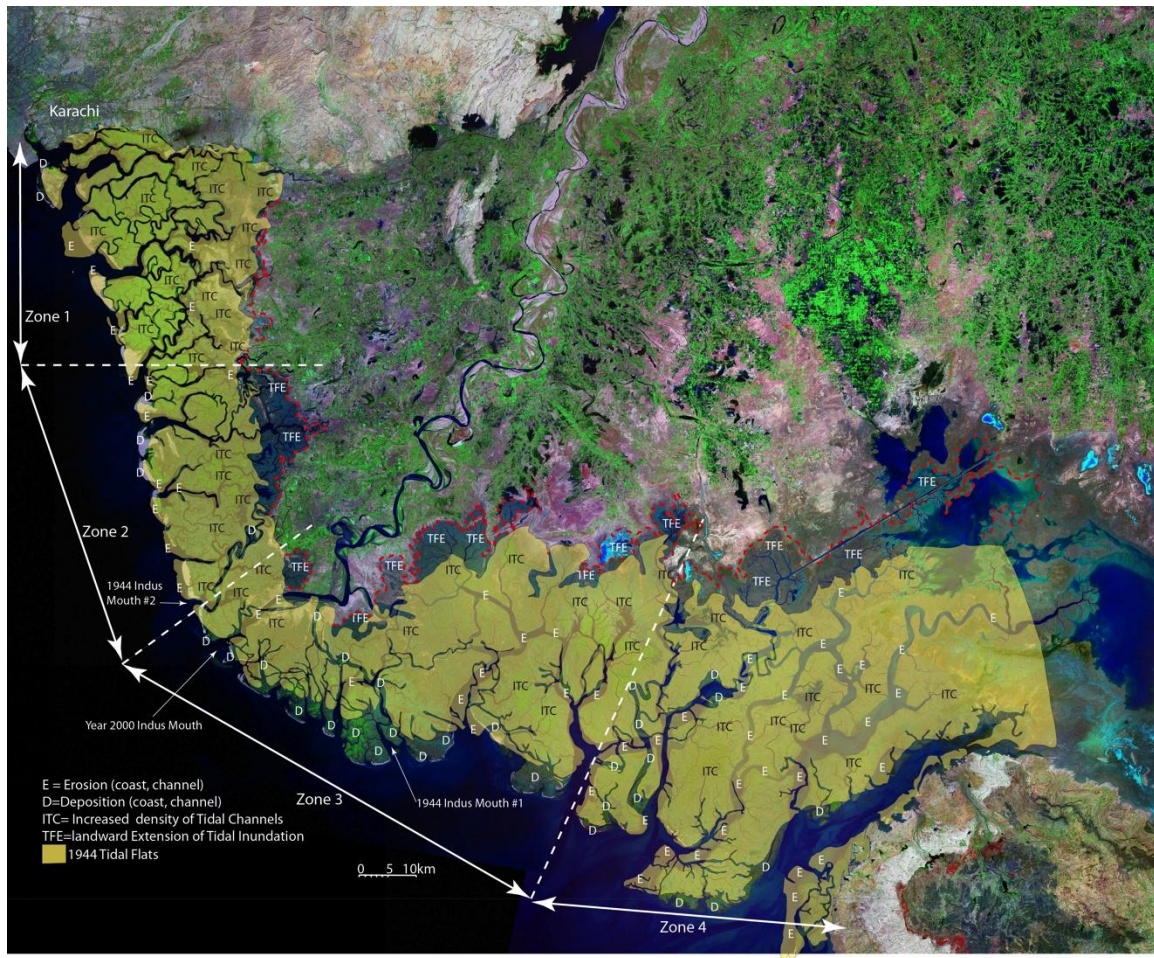

Figure 8. The background image is from a LANDSAT 7 composite of the Indus Delta from the year 2000. Superimposed is the circa 1944 USACE high-resolution maps of the Indus Delta (see suppl. matl.) shown in transparent yellow. The year 2000 tidal channels can be seen through the 1944 overlay. The letter E indicates areas of post 1944 erosion. The letter D indicates areas of post 1944 sediment deposition. ITC indicate increased density of tidal channels since 1944. TFE indicates areas with tidal inundation expansion since 1944. See text for details.

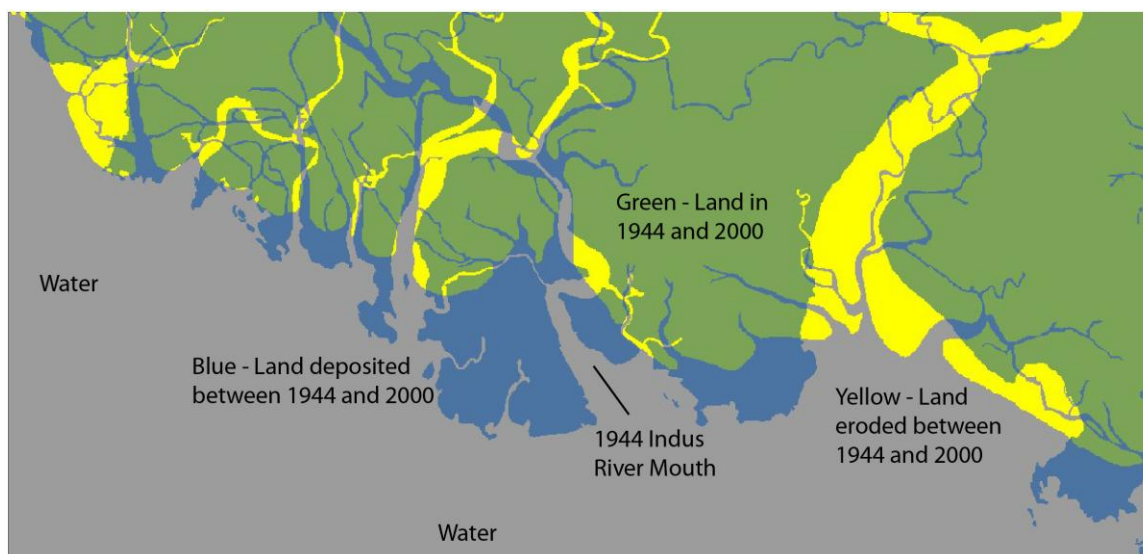

Figure 9: Small section of the Indus Delta showing the 1944 river mouth of the Indus (see Fig. 8). Yellow --- areas of net erosion between 1944 and 2000, blue --- areas of deposition, and green areas with no change.

*Figure 10: Eastern portion of the Indus Delta showing where sediment is tidally being pushed into the subsiding Lake Sindri (Pakistan and India) as tidal delta infill (TDI). Also shown is the uplifted Allah Bund from the earthquake of 1819.*

**Table 1:** Historical map information used in the construction of Fig. 5 (also see suppl. matl.) indicating the number of river mouths (12-17) and this decrease from 1900 into modern times where only one mouth of significance remains. The main historical channels are named. The RMS geo-location error is in m.

Year	River Mouths	Major Outlets	Outlet Name	Map Scale Reference		RMS Error (m)
