**Abstract**—Recently, new types of interference in electric vehicles (EVs), such as converters switching and/or battery chargers, have been found to degrade the performance of wireless digital transmission systems. Measurements show that such an interference is characterized by impulsive behavior and is widely varying in time. This paper uses recorded data from our EV testbed to analyze the impulsive interference in the digital audio broadcasting band. Moreover, we use our analysis to obtain a corresponding interference model. In particular, we studied the temporal characteristics of the interference and confirmed that its amplitude indeed exhibits an impulsive behavior. Our results show that impulsive events span successive received signal samples and thus indicate a bursty nature. To this end, we performed a data-driven modification of a well-established model for bursty impulsive interference, the Markov-Middleton model, to produce synthetic noise realization. We investigate the optimal symbol detector design based on the proposed model and show significant performance gains compared to the conventional detector based on the additive white Gaussian noise assumption.

**Index Terms**—Impulsive noise, Wireless communication, Machine learning, Electric vehicles

## I. INTRODUCTION

Electric Vehicles (EVs) represent a significant advancement towards sustainable transportation. However, integrating EVs into the broader mobility landscape introduces new challenges, particularly in the domain of electromagnetic interference (EMI) [1], [2]. In particular, the power devices in a DC-DC converter are inevitable to generate EMI and cause undesirable interference to the wireless communication systems [3], [4]. One critical area affected by EMI is the Digital Audio Broadcasting (DAB) system [5]. The emergence of EVs has underscored the need to understand and mitigate interference in DAB systems to ensure uninterrupted and high-quality broadcasting to these vehicles. To overcome the limitation imposed by the EMI and design an optimal receiver scheme, an accurate interference model is necessary.

The Middleton impulsive noise model [6], [7] is a common tool for EMI analysis. More recently, to describe the bursty nature of the interference, the Markov-Middleton model was proposed in [8], [9], which introduces a correlation between the impulse events. Moreover, the authors of [8] described an optimal symbol detector scheme for such a model based on the Bahl-Cocke-Jelinek-Raviv (BCJR) algorithm [10].

Nevertheless, the modeling of EV-induced interference has been largely unexplored. Crucially, due to the lack of simple and tractable models, optimal receiver designs for DAB systems have not been thoroughly investigated. In this study, we focused on characterizing via field test recordings and simulating via a modified impulsive interference model, the EMI generated by EVs, particularly emphasizing on the interference encountered in DAB systems. By analyzing the interference signatures, we found that the bursty impulsive EMI behavior is similar to the noise realizations from the Markov-Middleton model. We adopt a data-driven approach to estimate the key parameters for the Markov-Middleton model.

Our work establishes a comprehensive connection between the field-recorded EV interference in the DAB band and a well-established model using statistical analysis and machine learning tools. In more detail, we used the K-means algorithms to cluster the bursty events into background noise and multiple impulsive noise groups. After the algorithm has detected bursty events through an adaptive threshold over the field test data, we estimate the parameters for the modified Markov-Middleton model. Finally, we demonstrate how the inferred parameters can be used to design an optimal receiver for such an interference model.

The paper is organized as follows: Sec. II describes the experiment setup and received data characteristics. Sec. III introduces the Markov-Middleton model for communication over bursty impulsive channels. Sec. IV details the methods for impulse detection, burst capture, clustering, and model parameter estimation from the measurements. Sec. V presents

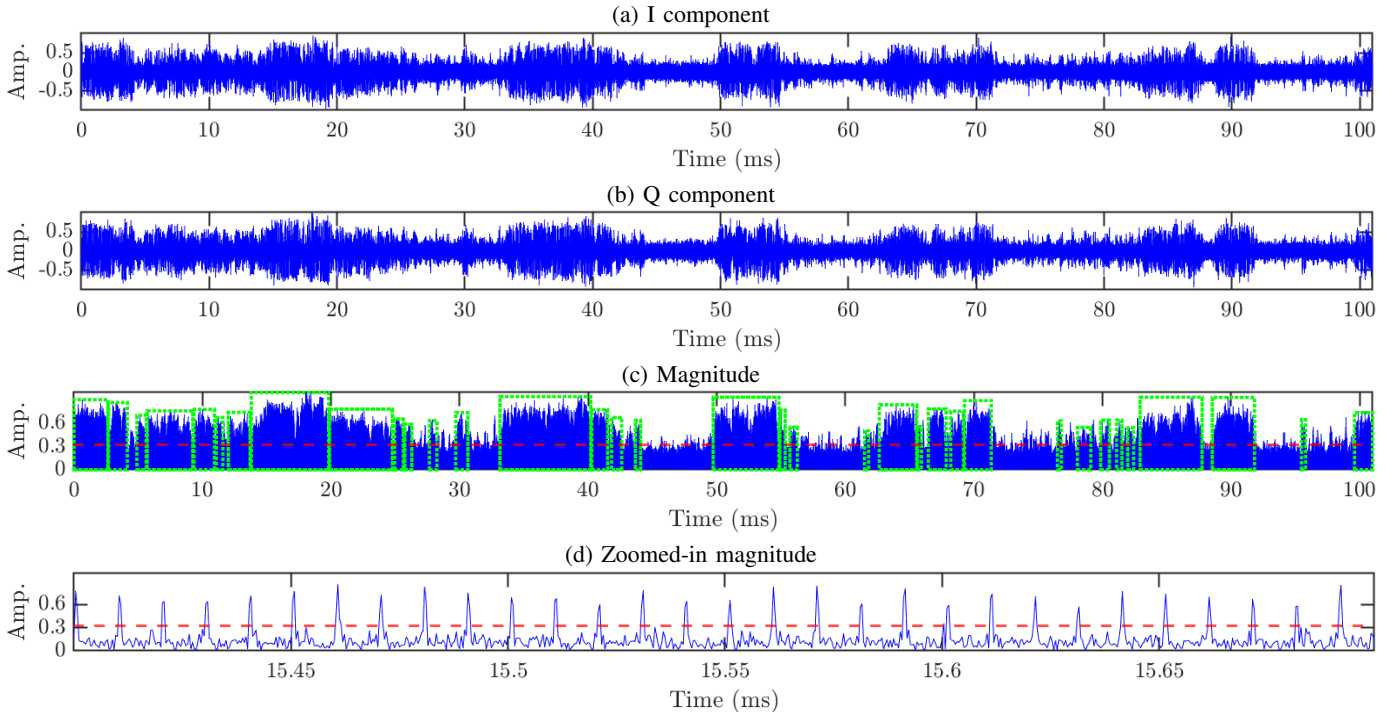

Fig. 1: (a) Real part, (b) Imaginary part, (c) magnitude, and (d) roomed in magnitude of the noise and interference measurements from our EV testbed. The green rectangular in (c) represents the captured bursty events with impulsive decision threshold marked with dashed red line

a modified Markov-Middleton model and numerical results for such a model. Sec. VI summarize the paper.

## II. EXPERIMENT SETUP AND IMPULSIVE NOISE MEASUREMENTS

### A. EV testbed

We employed a DAB signal recorder mounted on an EV with a dual antenna configuration installed on top of the vehicle to measure the EV interference within the DAB band. This recorder is operated at a 2.6 MHz sampling rate, where the carrier frequency can be adjusted from 174.928 MHz to 239.2 MHz depending on the desired DAB channel. After down-converting the received signal to baseband, the output data from the recorder is in IQ format, which represents the complex number. In our testbed, we also include a Global Positioning System (GPS) and an On-board Diagnostics (OBD) module to record the location and status of the car. These tools assist us in selecting the proper dataset for analyzing EV-induced internal interference.

### B. Impulsive noise characteristics

For illustration purposes, we assume our received signal as

$$Y = X + N + I, \quad (1)$$

where  $X$  is the transmitted DAB signal, and  $Y$  is the noisy received signal from our IQ recorder. Here, we assume  $N$  is the thermal noise, which follows a zero mean Gaussian distribution and is independent of the transmitted signal  $X$ .  $I$

represents an additive EV interference. We specifically choose an empty DAB channel ( $X = 0$ ) recording to focus on the analysis of the EV interference.

The time-domain data of our measurement, shown in Fig. 1, demonstrate a bursty impulsive behavior, where the sequence of impulsive noise samples is composed of correlated impulse events. This type of impulsive interference causes an elevated noise floor in the frequency domain due to its wideband characteristics, significantly affecting the detection capability of an Orthogonal Frequency Division Multiplexing (OFDM) system such as the DAB receiver. By looking into the consecutive impulsive samples in Fig. 1d, we found that each impulsive event is separated by a fixed duration of  $10 \mu\text{s}$ , likely generated by power electronic devices operated with 100 kHz.

## III. MARKOV-MIDDLETON MODEL

This section summarizes the Markov-Middleton model initially proposed for powerline communications [8]. This model addresses the statistical nature of bursty impulsive noise by incorporating the hidden Markov process into the notable Middleton Class A model. The measurement from our EV testbed shares similar time domain structures with this model, as illustrated in Fig. 1, offering a promising framework for modeling the bursty behavior of EV interference.

This model offers a tractable probability density function

Fig. 2: State diagram representation of a 4-state Markov-Middleton model

for the noise sample  $z$  as

$$p(z) = \sum_{m=0}^{M-1} \frac{p_m}{\sigma_m \sqrt{2\pi}} \exp\left(-\frac{z^2}{2\sigma_m^2}\right), \quad (2)$$

where

$$p_m = \frac{e^{-A} A^m / m!}{\sum_{m=0}^{M-1} e^{-A} A^m / m!} \quad (3)$$

and

$$\sigma_m^2 = \sigma^2 \frac{m/A + \Gamma}{1 + \Gamma}, \quad (4)$$

with  $M$  denoting the total number of noise states, including the background noise. Note that in this model, the noise sample  $z$  represents the joint effect of the thermal noise  $N$  and interference  $I$  in (1). The model parameters  $A$ ,  $\Gamma$ , and  $\sigma^2$  represent the impulsive index, the background-to-impulse noise ratio, and the total power of  $z$ , respectively. Moreover, the Markov-Middleton model includes a parameter  $r \in [0, 1]$  that establishes a correlation between noise samples. Then, the state transition matrix can be constructed as

$$P_{ij} = \begin{cases} r + (1-r)p_j, & i = j \\ (1-r)p_j, & \text{otherwise.} \end{cases} \quad (5)$$

The state transition diagram for a 4-state noise model is shown in Fig. 2, where the state  $S_0$  is denoted as the background

Fig. 3: Histograms of (a) I component and (b) Q component of the background noise from the measurements

Fig. 4: Histogram of the magnitude of the identified bursty events from the measurements. Three clusters based on the K-mean algorithm with blue, orange, and yellow bars, attributed to State-1, State-2, and State-3, respectively

noise. Given the state transition probability in (5), we can derive the mean duration (in samples) of each state as

$$d_m = \frac{1}{(1-r)(1-p_m)}, \quad m = 0, \dots, M-1. \quad (6)$$

As suggested in [8], the correlation parameter  $r$  is derived by measuring the average number of impulse-free consecutive samples. For  $m = 0$  in (6), we can derive  $r$  as

$$r = 1 - \frac{1}{d_0(1-p_0)}. \quad (7)$$

#### IV. PARAMETER ESTIMATION

The optimal receiver based on the Markov-Middleton model assumption requires accurate parameter estimation. To obtain this, we employed a data-driven approach and selected a representative dataset consisting of bursty events extracted from our measurements. We used this dataset to conduct a comprehensive statistical analysis, which enabled us to explore the connection with the Markov-Middleton model.

##### A. Impulsive noise detection

To statistically analyze impulsive noise, we must separate it from background noise. To this end, we establish an adaptive threshold as

$$th = \alpha \cdot W_{rms}, \quad (8)$$

where  $W_{rms}$  is the root mean square value of the received signal, and  $\alpha$  represents a scaling factor. The effectiveness of the selected threshold value  $th$  is assessed by analyzing the histogram of the IQ component of the determined background noise presented in Fig. 3. We observed that the histogram shape conforms reasonably well to a Gaussian distribution.

Fig. 5: Time domain synthetic bursty impulsive noise samples generated from the modified Markov-Middleton model with parameters in Table I

TABLE I: Estimated parameters from the measurements

State	0	1	2	3
$\hat{d}_m$	105	57	69	186
$\hat{p}_m$	0.54	0.13	0.11	0.22
$\hat{\sigma}_m$	0.010	0.066	0.112	0.183
$\hat{r}$	0.979			

### B. Bursty event detection

As was shown in Fig. 1, the EV-induced impulsive noise has a bursty nature, where impulses with a similar amplitude appear to occur over a consecutive time interval. In this study, we define a bursty event as a period of time where the signal amplitude surpasses the predefined threshold in (8). Such events are cataloged through the sequence of indices corresponding to the impulse samples. This study sets the minimum consecutive time for bursty events detection to 0.5 ms. In addition, the bursty event decision process allows a tolerance margin of  $0.3 \mu\text{s}$  for a non-impulsive period. As a result, we detected approximately 3600 bursty events within an 8-second recording time. These events are visually denoted by green rectangles in Fig. 1c.

### C. K-mean clustering

After identifying all the bursty events in our dataset, we can group them into a set of finite states for further parameter estimation for the Markov-Middleton model. Here, we use the one-dimensional K-mean clustering algorithm to differentiate the bursts into  $M - 1 = 3$  impulsive groups based on their average power. The resulting clusters are presented in Fig. 4, with the centroids of these clusters indicated by black dashed lines. We also observe that the magnitude distribution of the bursty events is similar to the exponential distribution found in [11]. After the clustering phase, every bursty event is labeled with a unique cluster ID, effectively differentiating the events based on their mean power. This process facilitates the analysis of impulsive noise in the measurements under the Markov-Middleton model framework by capturing its statistical properties.

### D. Model parameter estimation

To infer the probability of occurrence  $\hat{p}_m$  for each state from our measurements, we divide the count of bursty events attributed to each state by the total samples of the recording. The estimated mean duration  $\hat{d}_m$  of each state is obtained by counting the average number of samples in the bursts. It is important to note that the background noise ( $S_0$ ) exhibits

Fig. 6: BER performance of coded BPSK system with different detectors for the channel with 4-state bursty impulsive noise

the highest probability of occurrence. However, among the interference states, State-3 ( $S_3$ ) is the most probable, which we found to be different than the Markov-Middleton probability distribution in (3). This mainly results from the fact that the strongest interference state  $S_3$  also had the longest mean duration compared to the other impulsive states. Note that such an observation was also made by the authors of [11] regarding their power station measurements, and thus, it's not unusual in real-world EMI scenarios. Given the estimated mean duration  $\hat{d}_0$  and state probability  $\hat{p}_0$ , we can then calculate the correlation parameter  $\hat{r}$  using (7). We also compute the sample variance for each state from our measurements. The estimated parameters are listed in Table I.

## V. OPTIMAL DETECTOR PERFORMANCE

### A. Modified Markov-Middleton model

Given the parameters inferred from Sec. IV-D, we can now use the model to generate the synthetic bursty impulsive noise data. It is important to note that here, we use the data-inferred parameters  $\hat{p}_m$ ,  $\hat{\sigma}_m$ , and  $\hat{r}$  to compute the probability density function in (2) for each of the impulsive noise states. In contrast, in the original model, the density functions are calculated based on (3) and (4). The synthetic bursty impulsive noise output sample generated from our modified Markov-Middleton model is shown in Fig. 5.

### B. Optimal Detector Design

Based on the modified Markov-Middleton model, an optimal maximum a-posteriori detector can be designed to take the

interference states into account [8], [9]. This subsection evaluates the bit-error rate for an LDPC-coded binary phase-shift keying ( $X \in \{-1, 1\}$ ) system. The codeword length is 64800, and the code rate is 1/2. This communication system setting was also used in [8]. Results from Fig. 6 show that the IN detector, which incorporates the modified Markov-Middleton noise states, significantly outperforms the conventional AWGN detector that only considers the background noise state.

## VI. CONCLUSIONS

In this study, we employed a wideband recorder mounted in an EV to capture the interference plus noise signal in an empty DAB channel. By comprehensively analyzing the measurements, we identified the bursty impulsive nature of the interference and proposed a modified Markov-Middleton model with the parameters estimated from our recordings. This research contributes to providing a systematic analysis of EV-induced interference, thereby facilitating the development of robust receiver design. This study aims to bridge the gap between simple theoretical models and the real-world phenomena of EV interference.
