We describe a direct observation of the excitonic giant Zeeman splitting in Ga_{1-x}Mn_xN, a wide-gap III-V diluted magnetic semiconductor. Reflectivity and absorption spectra measured at low temperatures display the *A* and *B* excitons, with a shift under magnetic field due to *s,p-d* exchange interactions. Using an excitonic model, we determine the difference of exchange integrals between Mn³⁺ and free carriers in GaN, $N_0(\alpha - \beta) = -1.2 \pm 0.2$ eV. Assuming a reasonable value of α , this implies a positive sign of β which corresponds to a rarely observed ferromagnetic interaction between the magnetic ions and the holes.

PACS numbers: 75.50.Pp, 75.30.Hx, 78.20.Ls, 71.35.Ji

Diluted magnetic semiconductors (DMS) of the III-V type, such as (Ga,Mn)As, attract attention mainly because of their magnetic and electron transport properties. The direct measurement of the strength of the ion-carrier coupling, as routinely performed in II-VI DMS, through the observation of the giant Zeeman splitting of excitons, was not accessible for III-V DMS due to free carriers introduced by magnetic ions. Hence conclusions have been based on studies of extremely diluted samples¹ or on a complex interpretation of experimental data.^{2,3,4}

Here we show and quantitatively describe excitons in GaN, with a shift due to the *s,p-d* coupling to Mn ions incorporated as neutral centers (Mn³⁺). We present both the magneto-optical study of specially designed and thoroughly characterized Ga_{1-x}Mn_xN layers, and the excitonic model needed to determine the strength of ion-carrier coupling. Such a model is needed, because excitonic effects are especially strong in wide-gap semiconductors. Hence the giant Zeeman effect measured on the excitons cannot be identified with that of band-to-band transitions, as it has been done for other wurtzite DMS.⁵

Ga_{1-x}Mn_xN layers of about 400 nm-thick were grown by molecular beam epitaxy on sapphire substrates with a GaN or AlN buffer layer, along the *c*-axis perpendicular to the surface⁶. Details on the growth can be found in Ref. 7. Layers grown with a GaN buffer allowed to study quantitatively⁸ the infrared absorption due Mn³⁺, as identified in quasi-bulk crystals,⁹ and they exhibit⁸ magnetic circular dichroism (MCD) at the bandgap energy,¹⁰ due to the ion-carrier coupling. Layers with a higher Mn content evidence a ferromagnetic behavior at low temperature.⁷ The present Ga_{1-x}Mn_xN layers have been grown on a buffer layer made of AlN, which has a large energy gap (over 6 eV), so that the excitonic spectra of Ga_{1-x}Mn_xN (E_g about 3.5 eV) are not entangled with those of the buffer layer. The presence of the AlN buffer layer with a lattice mismatch introduces strain and disorder, which increases the excitonic linewidth. As disorder increases also with the Mn content, we focused our study onto rather dilute samples ($x < 1.2\%$) exhibiting well-resolved excitons.

The concentration of Mn³⁺ has been determined using near infrared spectroscopy. We observe sharp absorption lines previously reported^{8,9} as intra-ionic ${}^5T_2 \rightarrow {}^5E$ transitions of Mn³⁺. The intensity of these lines has been calibrated⁸ against secondary ion mass spectrometry (SIMS) in samples, where the d^4 configuration of Mn has been confirmed by x-ray absorption at the Mn K-edge.¹¹ In the present series of samples, the intensity of the Mn³⁺ absorption follows the total Mn concentration determined by SIMS with an accuracy better than 10%. Furthermore, a Mn²⁺ concentration lower than 0.01% was deduced from the absence of the characteristic lines in electron paramagnetic resonance spectra.¹²

In wurtzite GaN, the crystal field and the spin-orbit coupling split the valence band into three components, from which three excitons are formed, labeled *A*, *B*, and *C* in the order of increasing energy. There is a strong optical anisotropy. If the electric field *E* of the incident light is perpendicular to the *c*-axis (σ polarization), the oscillator strength is larger for excitons *A* and *B* than for exciton *C*. Exciton *C* has the largest oscillator strength if $E||c$ (π polarization). The position and oscillator strength of all excitons, and particularly exciton *C*, are modified by strain.¹³

We measured reflectivity at temperatures down to 1.7 K, with the light from a high-pressure Xe lamp incident along the *c*-axis. In this configuration only the σ polarization is accessible. In zero-field spectra, we observe two characteristic features. For the most diluted sample [$x = 0.01\%$, Fig. 1(a)], the energy of these features corresponds to the energy of the *A* and *B* excitons in GaN with a biaxial compressive strain of about 19 kbar using data from Ref. 13. Such a strain strongly reduces the oscillator strength of exciton *C*, which is also particularly sensitive to strain disorder. This explains why we do not observe a third structure at 3540 meV, as expected for exciton *C* at this strain value. In another sample with $x = 0.5\%$ [see the middle spectra marked as $B = 0$ in Fig. 1(b)], the *A* and *B* excitonic features are further broadened and shifted to higher energies. This shift confirms the increase of the bandgap energy upon increasing

FIG. 1: (Color online) (a) Reflectivity of A and B excitons measured for $\text{Ga}_{1-x}\text{Mn}_x\text{N}$ with $x = 0.01\%$. (b) Reflectivity, (c) absorption and (d) derivative of absorption, for $x = 0.5\%$, in Faraday configuration, in σ^+ (top, red color) and σ^- (bottom, blue color) circular polarizations, at $T = 1.7$ K.

FIG. 2: (Color online) Energies of excitonic transitions determined from reflectivity peaks (filled circles, blue color) and from derivative of absorption (empty circles, red color), at $T = 1.7$ K and $B||c$. the Mn content, previously inferred from MCD spectra.⁸

Magneto-optical spectra were measured in the Faraday configuration, with the magnetic field parallel to the common c -axis and optical axis. Magneto-reflectivity spectra of pure GaN or very diluted GaN:Mn ($x = 0.01\%$), not shown, exhibit a very small excitonic Zeeman shift, $\Delta E < 0.5$ meV, even at $B=11$ T, in agreement with previously reported data on GaN.^{14,15} The Zeeman shift of excitons is strongly enhanced in the presence of a significant content of Mn ions. This is shown in Fig. 1(b), which displays reflectivity spectra of the sample with $x = 0.5\%$, at 1.7 K and different values of the applied field. The σ^+ and σ^- circular polarizations are defined with respect to the direction of the applied field. Exciton A shifts to low energy (redshift) in σ^- polarization ($\Delta E = 6$ meV at $B=11$ T). In σ^+ , it shifts to high energy and merges with the B exciton. The behavior of exciton B is more complex, as shown by the plot of the positions of the reflectivity maxima shown in Fig. 2 (filled circles). Note also that the saturation of the redshift of A starts at quite high field values, when compared to other DMS.

Excitons A and B are observed also in absorption, Fig. 1(c). Excitonic features are more visible in the derivative of these absorption spectra, Fig. 1(d): the positions of the peaks are plotted in Fig. 2 as empty circles, using the right axis. They are shifted by 2 meV with respect to the maxima in reflectivity. The exact energy of the excitonic transitions is neither the energy of the reflectivity maxima (see the position of transverse polaritons in Ref. 16) nor that of the peaks in the derivative of the absorption spectra. However, since the shape of the excitonic features appears to be not affected by the applied field, selecting arbitrary a position within the observed feature results only in a constant shift. Hence we obtain a good estimate of the Zeeman shifts even if we do not know the absolute position of the exciton. This is confirmed by the agreement between the exciton evolution determined from the two kinds of spectra in Fig. 2.

We now turn to a detailed analysis of shifts such as observed in Fig. 2. It includes the proper description of the valence band and of excitons in GaN, the strength of the $s,p-d$ exchange interactions, and the magnetic properties of Mn in GaN.

We first briefly remind the different components entering the excitonic Hamiltonian and discuss necessary assumptions. In zero-field, the energy of a hole in the valence band of a semiconductor with the wurtzite structure is given by:¹⁷

$$H_v = -\tilde{\Delta}_1(L_z^2 - 1) - 2\Delta_2 L_z s_z - 2\Delta_3(L_x s_x + L_y s_y), \quad (1)$$

where $\tilde{\Delta}_1$ describes the effect of the trigonal components of crystal field and strain, and Δ_2 and Δ_3 the anisotropic spin-orbit interaction; L_α and s_α are projections of the orbital and spin momenta, respectively. The z direction is parallel to the c -axis.

Electron-hole interactions within the exciton results in $H_{e-h} = -R^* + 2\gamma \vec{s}_e \vec{s}_h$, where R^* is the binding energy, \vec{s}_e is the electron spin and \vec{s}_h the hole spin, and the

electron-hole exchange^{15,17} is parameterized by the exchange integral γ . A possible difference in the binding energies of the three excitons cannot be distinguished from a change in the values of $\tilde{\Delta}_1$ or Δ_2 above.

Both holes and electrons interact with the Mn ions through the so-called $s,p-d$ exchange. In this work we use the standard form of the $s,p-d$ Hamiltonian, which only depends on the relative orientation between the carrier spin and the averaged Mn spin $\langle \tilde{\mathbf{S}} \rangle$. It reads: $H_{s,p-d} = N_0(\alpha \tilde{\mathbf{s}}_e + \beta \tilde{\mathbf{s}}_h) x \langle -\tilde{\mathbf{S}} \rangle$, where α and β are the $s,p-d$ exchange integrals for electrons and holes, respectively. A more complex description of the $p-d$ interaction for the d^4 electronic configuration has been given in Ref. 18, but our experimental precision does not allow us to evidence any effect of the additional terms involving the orbital momentum. The direct influence of the magnetic field on the exciton (usual Zeeman effect and diamagnetic shift) can be also easily implemented in our model,¹⁵ but it is small enough to be safely neglected.

Finally, our Hamiltonian takes the following form: $H = E_0 + H_v + H_{e-h} + H_{sp-d}$, where E_0 is the bandgap energy. For a magnetic field parallel to the c -axis and light incident along the same direction, we limit ourselves to Γ_5 excitons optically active in σ polarization. The Hamiltonian separates into two operators acting in two subspaces corresponding respectively to excitons active in the σ^+ and σ^- circular polarizations. For σ^+ we use the following basis: $|s \downarrow p^+ \uparrow\rangle$ and $|s \uparrow p^+ \downarrow\rangle$ (which are identically active in σ^+ polarization and will give the main contribution to excitons A and B), and $|s \uparrow p^z \uparrow\rangle$ (which is optically inactive since it is spin-forbidden, but will give the main contribution to exciton C in σ polarization). In this basis the Hamiltonians are written:^{17,19,20}

$$H_v = \begin{pmatrix} -\Delta_2 & 0 & 0 \\ 0 & \Delta_2 & -\sqrt{2}\Delta_3 \\ 0 & -\sqrt{2}\Delta_3 & \tilde{\Delta}_1 \end{pmatrix}, \quad (2)$$

$$H_{e-h} = -R^* + \frac{\gamma}{2} \begin{pmatrix} -1 & 2 & 0 \\ 2 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (3)$$

$$H_{sp-d}^{\sigma^\pm} = \pm \frac{1}{2} N_0 x \langle -S_z \rangle \begin{pmatrix} \beta - \alpha & 0 & 0 \\ 0 & \alpha - \beta & 0 \\ 0 & 0 & \alpha + \beta \end{pmatrix}. \quad (4)$$

The same matrices, with opposite giant Zeeman terms, apply in σ^- polarization with the basis $|s \uparrow p^- \downarrow\rangle$, $|s \downarrow p^- \uparrow\rangle$, and $|s \downarrow p^z \downarrow\rangle$. We do not give the corresponding matrices for the other 6 excitons ($\Gamma_1, \Gamma_2, \Gamma_6$), which are not optically active in σ polarizations.

Diagonalizing the Hamiltonian gives the energy of the three excitons A, B and C in each circular polarization, as it is shown in Fig. 3(a). The corresponding oscillator strength marked by thickness of the line is deduced from the projection of the corresponding eigenvector, $|\psi\rangle$, onto the relevant subspace active in circular polarization: it

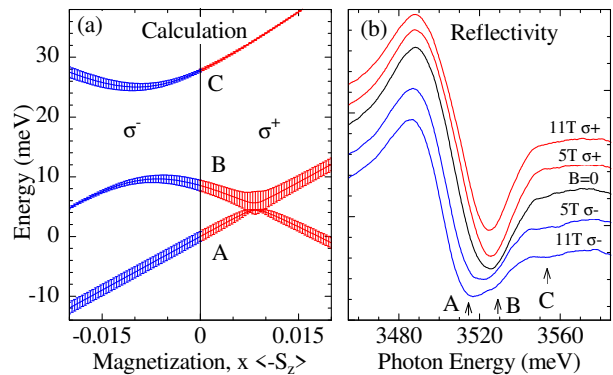

FIG. 3: (Color online) (a) Calculated energy of the A, B , and C excitons, vs. magnetization expressed as $x \langle -S_z \rangle$, for σ^- (left half) and σ^+ (right half) circular polarizations. Oscillator strengths are shown by bars. (b) Reflectivity of the sample with the highest Mn concentration ($x=1.2\%$). At zero field and in σ^+ polarisation excitonic structures are not resolved, but in σ^- polarization 3 structures can be distinguished in agreement with the model.

is proportional to $|\langle s \downarrow p^z \uparrow | \psi \rangle + \langle s \uparrow p^z \downarrow | \psi \rangle|^2$, for σ^\pm circular polarization, respectively.

Parameters used in Fig. 3(a) were determined as follows: using $\Delta_2 = 6.2$ meV, $\Delta_3 = 5.5$ meV and $\gamma = 0.6$ meV as reported for pure GaN,^{13,17} and keeping $\tilde{\Delta}_1$ and $N_0(\alpha - \beta)$ as free parameters, we fit the data in Fig. 2 using the mean spin of Mn^{3+} given in Ref. 8. We found $\tilde{\Delta}_1 = 17$ meV, larger than in relaxed GaN ($\tilde{\Delta}_1 = 10$ meV) due to compressive strain,¹³ and $N_0(\alpha - \beta) = -1.2 \pm 0.2$ eV. To plot Fig. 3(a) we used $N_0\alpha = 0.2$ eV, a typical value in DMS.

In zero field, the relative position of the excitons is determined mainly by the trigonal component of the crystal field including strain, $\tilde{\Delta}_1$, and the parallel spin-orbit interaction Δ_2 . The giant Zeeman shift of the exciton is induced by $s,p-d$ interactions. The electron-hole exchange interaction γ governs the anticrossing and mixing of the A and B excitons. It strongly alters the excitonic oscillator strength. The perpendicular spin orbit interaction (Δ_3) is responsible for the anticrossing and mixing between the B and C excitons. As a result, exciton C acquires a strong oscillator strength if the giant Zeeman splitting is large enough, as in the sample in Fig. 3(b).

An important result is that the giant Zeeman splitting of A and B excitons is not proportional to the Mn magnetization. In order to probe the giant Zeeman energy $[N_0(\alpha - \beta) x \langle -S_z \rangle]$, one should rather use the redshift of exciton A , which appears to be proportional to the magnetization as shown by the straight line in Fig. 3(a).

The redshift of A is well accounted for a large range of fields and temperatures, as shown in Fig. 4(a), where the mean spin of Mn^{3+} is calculated using Ref. 8. Both saturate only at the lowest temperature and highest magnetic field, as the field is applied along the hard magnetization axis of the strongly anisotropic Mn^{3+} ion. Any contribution of Mn^{2+} ions would saturate at low field (3 T),

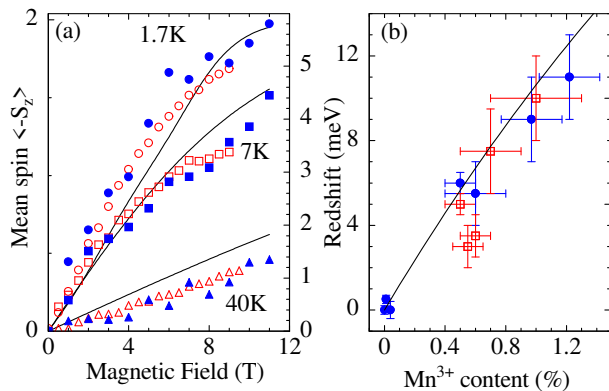

FIG. 4: (Color online) (a) Redshift of the A exciton determined using reflectivity (full symbols, blue color) and absorption (empty symbols, red color), compared to the mean spin of Mn³⁺ (solid lines, right axis) calculated using Ref. 8, for temperatures 1.7, 7, and 40 K. (b) Giant Zeeman shift of exciton A at saturation, determined using reflectivity (full circles, blue color) and absorption (empty squares, red color). Solid line represents value of the shift $\Delta E_A = -1/2N_0(\alpha - \beta)x_{\text{eff}}\langle -S_z \rangle$ calculated with $N_0(\alpha - \beta) = -1.2$ eV, $\langle -S_z \rangle = 2$, $x_{\text{eff}} = x(1 - x)^{12}$.

as does the Brillouin function for d^5 . We do not observe such a contribution, in agreement with our estimate of a negligible Mn²⁺ content.

This magneto-optical study was extended to a whole series of samples. As expected, the giant Zeeman shift increases with the Mn³⁺ content determined from d - d absorption. In Fig. 4(b), it is compared as usual to the effective concentration $x_{\text{eff}} = x(1 - x)^{12}$ rather than the total concentration x in order to account for the small non linear variation of A Exciton redshift. x_{eff} describes the density of Mn impurities with no magnetic ion over the 12 nearest-neighbors present in the Ga sublattice.

The redshift of exciton A in σ^- polarization unambiguously points to a negative sign of $N_0(\alpha - \beta)$. So far, $N_0\alpha$ has been reported to be small (< 0.3 eV) and

almost constant for all DMS, and there are no theoretical hint that the case of GaN-based DMS could be different. Then, $N_0(\alpha - \beta) = -1.2$ eV means that β is positive for GaN:Mn³⁺. If we assume a usual value, $N_0\alpha = 0.2 \pm 0.1$ eV, we deduce $N_0\beta = +1.4 \pm 0.3$ eV, which means a strong ferromagnetic interaction between the magnetic ions and the holes. A positive β was rarely observed in DMS, but^{21,22} for Cr in II-VI DMS, where Cr has the same $3d^4$ electronic configuration as Mn³⁺ in GaN. This suggests that a less than a half-filled d -shell could be responsible for a positive β . However this analogy could be misleading, because the energy position of donor and acceptor levels governs the sign of β (Refs. 18,23). As ionization levels are at higher energy in Mn²⁺ than in Mn³⁺ (see Ref. 24), we expect that Mn²⁺ in GaN exhibit also a positive β , despite its $3d^5$ electronic configuration. It is interesting to note however that observed magneto-optical giant Zeeman effect is in disagreement with the negative value of $N_0\beta$ deduced from photoemission experiments⁴ analyzed assuming an incorporation of Mn atoms as Mn²⁺.

To sum up, the giant Zeeman effect of the A and B excitons has been observed by reflectivity and absorption on a series of Ga_{1-x}Mn_xN samples. It is well described using an excitonic model valid for a DMS with the wurtzite structure, and values of the $s,p-d$ exchange integrals such that $N_0(\alpha - \beta) = -1.2 \pm 0.2$ eV. Assuming a reasonable value of α we find a positive sign of β , which means a ferromagnetic interaction between Mn³⁺ and holes in GaN.

We thank P. Sati, A. Stepanov for valuable data obtained by EPR technique. We acknowledge W. Bardyszewski, T. Dietl, and P. Kacman for helpful discussions. The work done in Grenoble was carried out in the CNRS-CEA-UJF Joint Group "Nanophysique et semiconducteurs". This work was partially supported by Polish Committee for Scientific Research (Grants No. N202 006 31/0153 and N202 123 31/1953) and by the French Ministry of Foreign Affairs.
