The Nuvvuagittuq Greenstone Belt (NGB) in Northern Quebec, Canada, is dominated by mafic and ultramafic rocks metamorphosed to at least upper amphibolite facies. Rare felsic intrusive rocks provide zircon ages of up to ~3.8 Ga (David et al., 2009; Cates and Mojzsis, 2007) establishing the minimum formation age of the NGB as Eoarchean. Primary U-rich minerals that may provide reliable formation ages for the dominant mafic lithology, called the Ujaraaluk unit, have yet to be found. Metamorphic zircons, rutiles and monazites are present in the unit and give variably discordant results with ²⁰⁷Pb/²⁰⁶Pb ages ranging from 2.8 Ga to 2.5 Ga. The younger ages overlap 2686 ± 4 Ma zircon ages for intruding pegmatites (David et al., 2009) and Sm–Nd ages for garnet formation in the Ujaraaluk rocks suggesting this era as the time of peak metamorphism and metasomatism in the NGB, coeval with regional metamorphism of the Superior craton. Sm–Nd data for Ujaraaluk whole rocks scatter about a Sm/Nd vs. ¹⁴³Nd/¹⁴⁴Nd correlation (MSWD = 134) whose slope would correspond to 3.6 ± 0.2 Ga if interpreted as an isochron. This “isochron” is seen to consist of a series of younger ~3.2–2.5 Ga slopes for the different geochemical groups within the Ujaraaluk, emanating from a baseline distribution older than 4 Ga. The ¹⁴⁶Sm–¹⁴²Nd chronometer is less affected by metamorphism at 2.7 Ga because of ¹⁴⁶Sm extinction prior to ~4 Ga. Expansion of the ¹⁴²Nd dataset for the Ujaraaluk and associated ultramafic rocks continues to show a good correlation between Sm/Nd ratio and ¹⁴²Nd/¹⁴⁴Nd that corresponds to an age of 4388⁺¹⁵_{–17} Ma. The dataset now includes samples with superchondritic Sm/Nd ratios that extend the correlation to ¹⁴²Nd excesses of up to 8 ppm compared to the terrestrial standard with a total range in ¹⁴²Nd/¹⁴⁴Nd of 26 ppm. The upper Sm/Nd ratio end of the Ujaraaluk correlation is defined by rocks that are interpreted to be cumulates to compositionally related extrusive rocks indicating that this crystal fractionation had to occur while ¹⁴⁶Sm decay was active, i.e. well before 4 Ga. Intruding gabbros give ¹⁴³Nd and ¹⁴²Nd isochron ages of respectively 4115 ± 100 Ma and 4313⁺⁴¹_{–69} Ma, also supporting an Hadean age for the gabbros and providing a minimum age for the intruded Ujaraaluk unit. 3.6 Ga tonalites surrounding the NGB, 3.8 Ga trondhjemitic intrusive veins, and a 2.7 Ga pegmatite show a deficit in ¹⁴²Nd compared to the terrestrial standard. These felsic rocks plot to the low Sm/Nd ratio side of the Ujaraaluk isochron and do not show a correlation between their Sm/Nd and ¹⁴²Nd/¹⁴⁴Nd ratios, which can be explained if they are melts of ancient LREE-enriched mafic rocks, such as the Ujaraaluk, with the melting occurring after ¹⁴⁶Sm was extinct. A subset of least disturbed Ujaraaluk samples has coherent isotopic compositions for both short-lived and long-lived Nd isotopic systems giving ¹⁴³Nd and ¹⁴²Nd isochron ages overlapping within error of 4321 ± 160 Ma (MSWD = 6.3) and 4406⁺¹⁴_{–17} Ma (MSWD = 1.0), respectively. This age represents our best age estimate for the Ujaraaluk unit. The NGB thus preserves over 1.6 billion years of early Earth history including an expanse of mafic crust formed in the Hadean.

1. Introduction

The first billion years of Earth history is poorly presented in the rock record with most early terrains being Eoarchean in age, leaving the Hadean Eon almost devoid of available samples. Until recently, the only available samples older than 4.1 billion years old (Ga) were detrital zircons from the Jack Hills conglomerate (~4.4 Ga; Wilde et al., 2001). Although these zircons provide invaluable information about the early Earth, their host rocks

have been destroyed, leaving no direct samples of Earth's primordial crust. As a result, the nature of Earth's early crust and the processes responsible for its formation are largely conjecture. Other than these detrital zircons, rare occurrences of Eoarchean crust provide the only compositional constraints on the nature of Earth's early crust. These terrains include the Acasta Gneiss, Canada (4.03 Ga; Bowring and Williams, 1999), the Itsaq Gneiss Complex, Greenland (3.85–3.60 Ga; Nutman et al., 1996; Nutman and Friend, 2009), the Napier complex, Antarctica (3.95–3.8 Ga; Williams et al., 1986; Simon and Nigel, 2007), the Saglek-Hebron block, Labrador (3.78–3.73 Ga; Collerson, 1983; Schiotte et al., 1989), and the Anshan area, China (3.8 Ga; Song et al., 1996; Liu et al., 2008; Wu et al., 2008, 2009; Nutman et al., 2009). Earth's primitive crust is most likely to have been derived from the partial melting of the mantle to produce an early mafic crust. This is consistent with the Lu–Hf isotopic compositions of the Jack Hills zircons that suggest that their host rock was tonalite-trondhjemite-granodiorite (TTG) derived from the melting of a basaltic Hadean precursor (Blichert-Toft and Albarede, 2008; Kemp et al., 2010).

Investigation of Earth's primitive crust and the timing of its formation have largely focused on felsic rocks because they are the most likely host rocks for the zircons that provide robust geochronological constraints. These felsic rocks, however, cannot have been directly produced by melting of mantle peridotite. Instead, they likely were produced by melting of an older mafic precursor. Using zircon ages from felsic rocks to provide geochronological constraints on suites of mafic rocks requires a very accurate understanding of the geologic relationships between the different lithologies. Stratigraphic relationships between felsic and mafic units are rarely unequivocal in early Archean terrains that generally have been affected by multiple phases of intense deformation and metamorphism. This emphasizes the need to focus on the mafic component in Eoarchean/Hadean terrains in order to constrain the composition and the timing of formation of Earth's earliest crust. Unfortunately, obtaining accurate ages on old terrestrial mafic rocks is difficult due to their lack of zircon, the common recrystallization of their original igneous mineralogy during later metamorphic events, and their generally low concentrations of the incompatible-element-based radiometric systems used for dating. While long-lived isotopic systems such as ^{147}Sm – ^{143}Nd , ^{176}Lu – ^{176}Hf and ^{187}Re – ^{187}Os are powerful tools to study the evolution of the crust–mantle system through time, Eoarchean/Hadean terrains usually have suffered extensive metamorphism and deformation that can affect these geochronometers through metamorphic/metasomatic redistribution of parent and/or daughter element any time after rock formation. On the other hand, the short-lived ^{146}Sm – ^{142}Nd isotopic system (half life = 68 Ma; Kinoshita et al., 2012) is not as susceptible to partial resetting because ^{146}Sm became extinct prior to ~4 Ga. Thus the ^{146}Sm – ^{142}Nd system is an ideal tool to probe any potential Hadean terrain. ^{142}Nd deficits recently have been identified in the Nuvvuagittuq Greenstone Belt (NGB) mafic rocks (O'Neil et al., 2008) suggesting an age of nearly 4.3 Ga, which would make it the only known remnant of Hadean crust preserved on Earth. However, the oldest U–Pb age obtained in zircon from rare intrusive felsic rocks in the NGB is 3817 ± 16 Ma (David et al., 2009). Nevertheless, the NGB offers a unique opportunity to constrain the composition of Earth's early crust and the processes responsible for the formation of crust in the Eoarchean/Hadean.

In this paper, we present an isotopic study combining both Nd long-lived and short-lived systems (^{147}Sm – ^{143}Nd , $T_{1/2} = 106$ Ga and ^{146}Sm – ^{142}Nd , $T_{1/2} = 68$ Ma) focusing on the mafic and ultramafic rocks of the NGB to put as many geochronological constraints as possible on the formation and evolution of the main lithology in the belt.

2. Geologic setting

The Nuvvuagittuq Greenstone Belt is located in Northern Quebec, Canada within the Hudson Bay terrane of the Northeastern Superior Province (Fig. 1). The Hudson Bay terrane is a TTG-greenstone terrain subdivided into different domains (Tikkerutuk, Bienville, Goudalie, La Grande, southern Douglas Harbour domains) and characterized by Nd model ages generally older than 3.0 Ga (Boily et al., 2009). The old rocks of the terrane are intruded by a series of younger TTG (~2.7 Ga) with low initial $^{143}\text{Nd}/^{144}\text{Nd}$ suggesting recycling of older crust (Boily et al., 2009). The Hudson Bay terrane is interpreted to represent a cratonic nucleus of the Northeast Superior Province onto which the more juvenile rocks of the Rivière Arnaud terrane were juxtaposed. The NGB is a ~10 km² volcano-sedimentary sequence preserved on the East shore of Hudson Bay approximately 35 km south of the Inuit municipality of Inukjuak. The NGB is dominantly composed of mafic to ultramafic rocks with chemical sedimentary rocks and minor felsic components, all highly deformed and metamorphosed. The map pattern of the NGB (Fig. 1) is dominated by a large-scale North-closing synform plunging moderately to the South. The West limb of this open fold consists of a tight isoclinal South-closing synform with a steeply E-plunging fold axis. The NGB has been metamorphosed to at least upper amphibolite facies. Cates and Mojzsis (2009) proposed that the NGB experienced at least two significant metamorphic episodes around 3.6 Ga and 2.7 Ga based on overgrowth of zircons, with the Neoproterozoic event reaching 640 °C.

The NGB is dominated by mafic rocks. The most abundant lithology is a heterogeneous, but generally basaltic, group of rocks mainly composed of variable proportions of cummingtonite–biotite–plagioclase–garnet. Due to its important variation in mineralogy, we refer to this lithological unit as the Ujaraaluk unit (formerly called the faux-amphibolite; O'Neil et al., 2007, 2008) that comprises facies that include both cummingtonite-rich rocks and rocks that are dominated by a garnet–biotite paragenesis. Despite this wide range in mineralogical proportions, the different parageneses of the Ujaraaluk unit show a relatively small range of major element composition from basaltic to basaltic andesite (O'Neil et al., 2011a) reinforcing their grouping as a lithological unit. The Ujaraaluk unit can be subdivided into three distinct geochemical groups mainly based on Al/Ti ratios and trace element profiles. These geochemical groups follow a chemical stratigraphy within the NGB with a high-Ti group that has relatively flat normalized incompatible trace element profiles at the base of the tight synform followed by a low-Ti group stratigraphically above. Chemical sediments lie at the transition between the high-Ti and the low-Ti Ujaraaluk groups. The low-Ti Ujaraaluk unit is further subdivided into two subgroups with distinct Al/Ti ratios and trace element profiles referred as the depleted low-Ti group and the enriched low-Ti group based on their relative concentration of incompatible trace elements (O'Neil et al., 2011a). Rocks from the low-Ti Ujaraaluk unit directly above the chemical sediments have lower concentrations of incompatible trace elements and distinct U-shaped rare earth element (REE) profiles, whereas the rocks from the low-Ti Ujaraaluk at the top of the sequence have the most enriched REE profiles (O'Neil et al., 2011a). The Ujaraaluk unit as a whole is interpreted by O'Neil et al. (2011a) to represent hydrothermally altered mafic volcanic crust transitioning from rocks with tholeiitic affinities to rocks with boninitic and calc-alkaline affinities deposited in a submarine volcanic environment. This is supported by the presence of deformed, but well-preserved pillows within the Ujaraaluk unit. The SW corner of the NGB contains massive aphanitic basaltic greenstones mainly composed of chlorite–epidote–quartz–plagioclase–actinolite (O'Neil et al., 2007). These greenstones can be divided into the same three compositional groups seen in the Ujaraaluk unit with the same

Fig. 1. Geologic map of the NGB. Coordinates are in UTM NAD 27.

geochemical characteristics [Fig. 1 Supplementary Data (SD1)] and following the same stratigraphy within the NGB. They are interpreted to be a lower grade, most likely retrograde, metamorphic equivalent to the Ujaraaluk unit. This interpretation is supported by the presence of these same greenstones to the SE of the NGB where they contain relicts of garnets completely chloritized that display

the same mineral texture observed in the garnet-rich Ujaraaluk rocks.

The Ujaraaluk unit includes ultramafic bodies that can be divided into the same three distinct geochemical groups following the same chemical stratigraphy as the Ujaraaluk mafic rocks (O'Neil et al., 2011a). These ultramafic bodies are interpreted to

be ultramafic sills. They mainly consist of serpentine-rich interiors with amphibole-rich margins and locally exhibit amphibole-rich layers within the ultramafic interiors. The composition of the ultramafic rocks follow a well defined olivine-fractionation line and are interpreted to be ultramafic cumulates cogenetic with corresponding mafic Ujaraaluk groups sharing the same geochemical trends and characteristics (O'Neil et al., 2007, 2011a). The Ujaraaluk unit also is intruded by numerous highly deformed gabbroic sills. These mafic intrusions are composed of plagioclase and hornblende. They can reach ~100 m in width and can sometimes be followed continuously over 1 km.

Rare trondhjemitic rocks intruding the southern extremity of the NGB were dated at 3751 ± 10 Ma (Cates and Mojzsis, 2007), 3817 ± 16 Ma (David et al., 2009) and 3774 ± 32 Ma (Darling et al., 2012) indicating that the NGB is at least Eoarchean in age. The NGB is surrounded by a 3661 ± 4 Ga foliated tonalite (David et al., 2009) locally intruding the NGB to the West, itself sheathed by younger (2750 ± 16 Ma) heterogeneous tonalities from the Tikkerutuk domain (Simard et al., 2003). The NGB also is intruded by Neoproterozoic pegmatitic sheets that provide zircon dates of 2686 ± 4 Ma (David et al., 2009). David et al. (2009) obtained U-Pb ages in zircons from a gabbro associated with the tonalite in the center of the synform and from a plagioclase-quartz-biotite schist. These samples yielded ages of 2693 ± 3 Ma and 3366 ± 2.5 Ma respectively, interpreted to be metamorphic ages.

Zircons from what is interpreted to be a conglomeratic unit in the NGB yield $^{207}\text{Pb}/^{206}\text{Pb}$ ages ranging from 3770 Ma to 3258 Ma (David et al., 2009). These zircons lie along a discordia with an upper intercept of 3787 ± 25 Ma. These conglomeratic units, however, are found only within high-strain zones and always within less than 100 m of the southern NGB-tonalite boundary making their relationship with the adjacent lithologies and exact origin equivocal.

Controversy about the age of the NGB emerged after O'Neil et al. (2008) showed that the Ujaraaluk unit had a deficit in ^{142}Nd relative to the terrestrial standard Nd. Unlike most occurrences of variable ^{142}Nd in early Earth rocks, the NGB rocks show a correlation between $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{147}\text{Sm}/^{144}\text{Nd}$ that, if interpreted as an isochron yields an age of 4.37 Ga [an age of 4.28 Ga was reported by O'Neil et al. (2008), but all ^{146}Sm - ^{142}Nd ages reported in this paper are calculated using the newly determined ^{146}Sm half life of 68 Ma and recalculated Solar system initial $^{146}\text{Sm}/^{144}\text{Sm} = 0.0094$ (Kinoshita et al., 2012)]. An Hadean age for the Ujaraaluk unit is supported by a $^{143}\text{Nd}/^{144}\text{Nd}$ vs. $^{147}\text{Sm}/^{144}\text{Nd}$ isochron for intruding gabbros that provides an age of over 4.1 Ga for these intrusive units. While the surrounding and intruding felsic lithologies of the NGB suggest an Eoarchean age, the dominant mafic lithologies yield an Hadean isotopic signature suggesting that the NGB could represent the oldest preserved crust on Earth.

3. Analytical procedures

Weathered surfaces and quartz veins were removed from rock samples prior to crushing. Weathering-free samples were crushed in a steel jaw crusher and then ground to powder in an alumina shatter box. Some samples contain coarse-grained garnet and therefore, to obtain representative whole rock powders, large size samples (15–20 cm) were crushed.

Whole rock samples were digested using a flux-fusion technique. Between 250 and 350 mg of powdered sample was fused in graphite crucibles using ~0.8 g of a mixture of 67% lithium tetraborate–33% lithium metaborate and ~0.02 g of lithium bromide for 20 min at 1050 °C. The molten beads were poured into a Teflon beaker containing 40 ml of 2 M HNO_3 and stirred for 20 min until the glass was completely dissolved. The dissolved samples were filtered to remove flakes of graphite from the crucibles.

Aliquots of this solution corresponding to 10% of the dissolved sample were spiked with enriched ^{150}Nd – ^{149}Sm tracers to measure the Sm and Nd concentrations by isotope dilution. The remaining 90% of the dissolved sample was not spiked and was used for Nd isotope measurements (^{142}Nd and ^{143}Nd). From both spiked and unspiked aliquots of the dissolution solution, the REE were precipitated by raising the pH of the HNO_3 solution to between 5.5 and 6 by the addition of NH_4OH . An Fe solution prepared from 99.9% anhydrous Aldrich FeCl_2 was previously added to both spiked and unspiked dissolved fractions to facilitate the precipitation. The precipitates were re-dissolved in 2.5 M HCl and loaded onto primary columns (1 cm \times 20 cm) filled with 200–400 mesh AG50W-X8 cation-exchange resin for the REE extraction. Sm and Nd were extracted from this REE fraction using methylacetic acid as described in Boyet and Carlson (2005). Both Sm and Nd were extracted from the spiked aliquot with one pass through the methylacetic acid columns whereas only the Nd was extracted on the unspiked aliquots but with three passes through the methylacetic acid columns in order to remove as much Ce and Sm as possible. Six Ujaraaluk samples also were measured for their unspiked Sm isotopic compositions to check for possible neutron irradiation or meteoritic components in these rocks. All six samples showed Sm isotopic compositions within error of the terrestrial standard (Table SD1). For the samples from barrel B369 and higher (see Table SD2), the Nd fractions for both spiked and unspiked aliquots obtained after methylacetic acid columns were then purified by passing the samples through columns filled with 300 mg of Eichrom Ln Resin 50–100 μm . No variation within error of the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios has been observed for duplicate samples (Table SD3) that have been purified with Eichrom Ln Resin.

Garnet separates were obtained after sieving of the crushed rock samples to collect a grain fraction between 120 μm and 75 μm . The grains were washed and garnets were separated from the other grains by magnetic separation. The cleanest garnet grains were then handpicked under a binocular microscope to avoid composite grains. This cleaner garnet fraction was leached following Pollington and Baxter (2010) to remove inclusions and then powdered using an agate mortar/pestle. Garnet samples (~65 mg) were digested in Parr bombs under pressure with a HF– HNO_3 mixture in Teflon containers.

Whole rock samples for Lu–Hf analysis were fused and precipitated using the same procedure as for the Sm–Nd. Samples were spiked with enriched tracers of ^{176}Lu and ^{178}Hf . The spike solution was added in the Teflon beaker with 40 ml of 2 M HNO_3 before pouring of the fused bead to assure spike-sample equilibration. Garnet separate samples were spiked for both Sm–Nd and Lu–Hf within the same dissolution. The Hf and Lu were collected and purified following procedures from Carlson et al. (2006).

Sm and Nd isotopic compositions were measured using double Re filaments in the Department of Terrestrial Magnetism (DTM) Thermo-Fisher Triton thermal ionization mass spectrometer. Mass spectrometric procedures followed those described in Carlson et al. (2007). The $^{147}\text{Sm}/^{144}\text{Nd}$ ratios as well as the Sm and Nd concentrations reported in Table 1 were measured on the spiked aliquots whereas all other reported isotopic data were obtained on the unspiked aliquots. Nd is measured as Nd^+ in a two-step dynamic routine that provides static measurements of all Nd isotope ratios and ^{138}Ba , ^{140}Ce , ^{141}Pr , and ^{147}Sm , and also provides a dynamic measurement for $^{142}\text{Nd}/^{144}\text{Nd}$. Individual runs consist of 540 ratios taken with 8 second integrations per mass step. When the amount of Nd on the filaments allowed, samples were run more than once on the same filament. Samples that were run multiple times from the same filament were combined into one run of 540+ ratios. Data were corrected for instrumental mass fractionation using the exponential law to $^{146}\text{Nd}/^{144}\text{Nd} = 0.7219$. Total Nd blank for the flux-fusion technique is 2.6 ng. Considering

Table 1

Nd isotopic data for the NGB rocks and mineral separates. $\epsilon\text{Nd}_{(t)}$ values were calculated at 4300 Ma for the Ujarraluk and Greenstone, at 4115 Ma for the gabbro, at 3660 Ma for the tonalite, at 3800 Ma for the trochjhemite band and at 2700 Ma for the pegmatite.

Sample	Lithology	[Nd] (ppm)	[Sm] (ppm)	$^{147}\text{Sm}/^{144}\text{Nd}$	$^{143}\text{Nd}/^{144}\text{Nd} \pm 2\sigma$	$\epsilon\text{Nd}_{(t)}$	T_{DM} (Ga)	$^{142}\text{Nd}/^{144}\text{Nd} \pm 2\sigma$	$\mu^{142}\text{Nd} \pm 2\sigma$

^a Data from O'Neil et al. (2008).

^b Data from David et al. (2009).

^c Average $\mu^{142}\text{Nd}$ value for duplicate samples (see Table SD3).

^d Average $\mu^{142}\text{Nd}$ value for duplicate samples including data from O'Neil et al. (2008) (see Table SD3).

2σ errors for $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{142}\text{Nd}/^{144}\text{Nd}$ are in the last decimal place.

that between 700 and 500 ng of Nd were analyzed for a sample, the Nd blank represents at most 0.5% of the total Nd analyzed. Repeated measurements of the JNdi-1 standard yielded a long-term dynamically measured value of $^{142}\text{Nd}/^{144}\text{Nd} = 1.1418354$ ($n = 41$, with most JNdi-1 standards analyzed twice on the same filament) with an external reproducibility (2σ , not 2σ -mean) of 4.5 ppm for the period of the study (Table SD4). The chondritic reference values used for εNd calculations are; $^{143}\text{Nd}/^{144}\text{Nd}_{\text{CHUR}} = 0.51263$, $^{147}\text{Sm}/^{144}\text{Nd}_{\text{CHUR}} = 0.196$ (Bouvier et al., 2008). Values used for Nd model age calculations are present day $^{143}\text{Nd}/^{144}\text{Nd} = 0.51301$ and $^{147}\text{Sm}/^{144}\text{Nd} = 0.2085$ reflecting a non-chondritic bulk Earth composition that today would have the 18 ppm excess $^{142}\text{Nd}/^{144}\text{Nd}$ observed in the modern terrestrial mantle compared to average ordinary chondrite (Carlson and Boyet, 2008). Initial $\varepsilon^{143}\text{Nd}$ and uncertainty were calculated following Fletcher and Rosman (1982). Initial $\mu^{142}\text{Nd}$ were determined from isochrons and normalized to a depleted mantle (DM) reservoir with $^{147}\text{Sm}/^{144}\text{Nd} = 0.2085$ and $\mu^{142}\text{Nd} = 0$. The decay constant used for ^{147}Sm is $6.54 \times 10^{-12} \text{ yr}^{-1}$ and $1.02 \times 10^{-8} \text{ yr}^{-1}$ for ^{146}Sm . For the ^{142}Nd analysis, corrections for both Ce and Sm interference were made prior to mass fractionation correction. $^{140}\text{Ce}/^{146}\text{Nd}$ ratios ranged from 8.4×10^{-7} to 8.3×10^{-4} with 52 out of 62 samples having $^{140}\text{Ce}/^{146}\text{Nd} < 10^{-4}$. The measured $^{147}\text{Sm}/^{146}\text{Nd}$ ratio during Nd runs averaged 3.1×10^{-6} with only 2 samples exceeding 1×10^{-5} . One sample (PC-220) yielded higher $^{140}\text{Ce}/^{146}\text{Nd}$ and $^{147}\text{Sm}/^{146}\text{Nd}$ ratios of 1.24×10^{-3} and 1.7×10^{-4} respectively.

The $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{147}\text{Sm}/^{144}\text{Nd}$ ratios for PC-085 (whole rock, hornblende and plagioclase separates) as well as the biotite separate for PC-276 were analyzed at the GEOTOP laboratories (Université du Québec à Montréal) following the procedure described in O'Neil et al. (2008)

The $\mu^{142}\text{Nd}$ [((($^{142}\text{Nd}/^{144}\text{Nd}$)_{sample} / ($^{142}\text{Nd}/^{144}\text{Nd}$)_{JNdi-1}) - 1) × 10⁶] for each sample was calculated using the average

($^{142}\text{Nd}/^{144}\text{Nd}$)_{JNdi-1} ratio within the same barrel used for sample analysis. In order to compare the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for samples from different barrels, the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for each sample reported in Table 1 were calculated using their $\mu^{142}\text{Nd}$ re-normalized to the long-term $^{142}\text{Nd}/^{144}\text{Nd}$ ratio for JNdi-1 of $^{142}\text{Nd}/^{144}\text{Nd} = 1.1418354$. The same re-normalization was applied to data from O'Neil et al. (2008) to allow comparisons of both studies. No correlation exists between $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{140}\text{Ce}/^{146}\text{Nd}$ or $^{147}\text{Sm}/^{146}\text{Nd}$ in samples or standards (Fig. SD3) suggesting that Ce and Sm interferences do not affect the data. Sample PC-220 has higher Sm and Ce interferences (Table SD2) but still does not display any correlation between $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{140}\text{Ce}/^{146}\text{Nd}$ or $^{147}\text{Sm}/^{146}\text{Nd}$ (Fig. SD3) and has a ^{142}Nd isotopic composition consistent with other samples from the same geochemical group. Sample PC-456 has the lowest $\mu^{142}\text{Nd}$ value (-18; Table 1) but with very small Sm and Ce interferences (Table SD2) and without any correlation between $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{140}\text{Ce}/^{146}\text{Nd}$ or $^{147}\text{Sm}/^{146}\text{Nd}$ (Fig. SD3) supporting the fact that the measured $\mu^{142}\text{Nd}$ values are not artifacts due to mass interferences and represent the real $^{142}\text{Nd}/^{144}\text{Nd}$ isotopic compositions of the samples. There also is no correlation between the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for the samples and their $^{145}\text{Nd}/^{144}\text{Nd}$, $^{148}\text{Nd}/^{144}\text{Nd}$, and $^{150}\text{Nd}/^{144}\text{Nd}$ ratios (Fig. SD4) indicating that the variability in $^{142}\text{Nd}/^{144}\text{Nd}$ ratio is not due to an incorrect mass dependency for the fractionation correction. Duplicate $^{142}\text{Nd}/^{144}\text{Nd}$ analyses are presented in Table SD3 and Fig. SD2. No variation within error of the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios is observed for duplicate samples. Duplicate samples also reproduce data from O'Neil et al. (2008) for the same sample. Table SD5 shows three ^{142}Nd duplicate analyses of samples from Isua analyzed previously by Rizo et al. (2011). The ^{142}Nd data obtained at DTM that range from $\mu^{142}\text{Nd}$ of +8 to +12 agree within error with the data reported by Rizo et al. (2011) on the same samples.

Lu–Hf measurements were performed on the DTM Nu-plasma multicollector-ICP-MS. Data are fractionation corrected to $^{179}\text{Hf}/^{177}\text{Hf}=0.7325$ and normalized to the average value of $^{176}\text{Hf}/^{177}\text{Hf}$ obtained for the JMC-475 Hf standard ($n=10$) during the same analytical session as the sample analyses. Values for $^{176}\text{Hf}/^{177}\text{Hf}$ for the JMC-475 standard ranged from 0.282139 to 0.282172 with an average value of 0.282152 ± 0.000022 (2σ , not 2σ -mean). All data are reported relative to $^{176}\text{Hf}/^{177}\text{Hf}=0.282160$ for the JMC-475 standard. Total Hf blank for the flux-fusion technique used for the whole rock measurements is 630 pg. The garnets were digested in Parr bombs where the total Hf blank is 88 pg. Although the Hf blank for the flux-fusion technique is higher, between 250 and 85 ng of Hf were analyzed for the whole rock samples. The Hf blank thus represents 0.7–0.3% of the total Hf analyzed. Table SD5 shows two Lu–Hf duplicate analyses of Isua samples previously reported by Rizo et al. (2011). The samples analyzed at DTM were dissolved using the flux-fusion technique and despite the higher blank, agree with the results reported by Rizo et al. (2011) within error.

U–Pb geochronology of zircons was conducted at the Laboratoire Magmas et Volcans, Clermont-Ferrand (France). Zircons were first identified directly on polished thin sections using a CAMECA SX 100 electron microprobe and then analyzed by laser ablation inductively coupled plasma spectrometry (LA-ICPMS). Analytical techniques for LA-ICPMS analysis are detailed in Table SD6. The method used for the zircon isotope dating with laser ablation ICP-MS followed the method developed for monazite by Tiepolo (2003) and Paquette and Tiepolo (2007). Concordia ages and diagrams were generated using Isoplot/Ex v. 2.49 software package by Ludwig (2001). The concentrations in U–Th–Pb were calibrated relative to the certified contents of the GJ-1 zircon standard (Jackson et al., 2004).

4. Results

4.1. ^{147}Sm – ^{143}Nd

4.1.1. Ujaraaluk unit and cogenetic ultramafic rocks

Samples from the three different geochemical groups of the Ujaraaluk unit, including samples from the greenstones, were analyzed for their ^{147}Sm – ^{143}Nd isotopic composition along with their respective cogenetic ultramafic sill samples (Table 1). The Ujaraaluk mafic rocks display a wide range of $^{147}\text{Sm}/^{144}\text{Nd}$ ratios from substantially subchondritic to slightly superchondritic (0.1257–0.2143) with $^{143}\text{Nd}/^{144}\text{Nd}$ isotopic compositions ranging from 0.510976 to 0.513219. The ultramafic sills have higher $^{147}\text{Sm}/^{144}\text{Nd}$ ratios ranging from 0.1603 to 0.2452 with more radiogenic $^{143}\text{Nd}/^{144}\text{Nd}$ compositions from 0.511894 to 0.513658. Sample PC-214 has a significantly more radiogenic isotopic composition compared to the rest of the ultramafic samples with a $^{147}\text{Sm}/^{144}\text{Nd}$ ratio of 0.2681 and a $^{143}\text{Nd}/^{144}\text{Nd}$ ratio of 0.514124. This is a sample of a layer of metamorphic orthopyroxene within an ultramafic sill, which may replace an original magmatic cumulate layer. A ^{147}Sm – ^{143}Nd isochron fit to all Ujaraaluk and cogenetic ultramafic samples yields an age of 3598 ± 200 Ma (Fig. 2A) with an initial ϵNd value of -1.0 ± 0.7 . This isochron, however, displays considerable scatter (MSWD = 134) and breaks down into a series of individual correlations with different slopes corresponding to the different geochemical groups within the Ujaraaluk (Fig. 2A). The ^{147}Sm – ^{143}Nd correlation lines fit separately for the high-Ti Ujaraaluk, the depleted low-Ti Ujaraaluk and the enriched low-Ti Ujaraaluk, along with their respective cogenetic ultramafic rocks, yield ages of 3257 ± 300 Ma, 2517 ± 240 Ma and 3734 ± 300 Ma respectively (Fig. 2B–D). The isochron for the enriched low-Ti Ujaraaluk samples can be further broken down into 2 distinct slopes

with younger ages of 2844 ± 460 Ma and 2685 ± 470 Ma respectively. These ages have been calculated with the exclusion of 2 high-Ti Ujaraaluk (PC-058, PC-451) samples and one depleted low-Ti Ujaraaluk (PC-214) sample. These samples lie well off the best fit lines defined by the remaining samples. We interpret this as reflecting post-magmatic processes that are further discussed in Section 5.2. The Ujaraaluk/ultramafic sills display a wide range of depleted-mantle model ages (T_{DM}) mainly ranging from 3.6 Ga to 4.5 Ga. A few samples have $T_{\text{DM}} \geq 4.5$ Ga most likely due to their near depleted-mantle Sm/Nd ratios resulting in an isotopic evolution trend that is sub-parallel to the depleted mantle evolution line. Samples with T_{DM} values between 3.6 Ga and 4.5 Ga have a bimodal distribution with groupings around 3.9 Ga and 4.3 Ga (Fig. 3A).

4.1.2. Central gabbro sills

Gabbro sill samples were collected toward the center of the tight synform. These gabbros display a distinctive fine-scale gneissosity defined by plagioclase-rich and amphibole-rich bands. The gabbros have chondritic to slightly unradiogenic Nd isotopic compositions with $^{147}\text{Sm}/^{144}\text{Nd}$ ratios ranging from 0.2034 to 0.1424 and $^{143}\text{Nd}/^{144}\text{Nd}$ ranging from 0.512909 to 0.511233 (Table 1). They define a relatively good isochron (MSWD = 7.2) yielding an age of 4095 ± 130 Ma ($n=14$) (Fig. 2E). Only one sample (PC-522) lies off the best fit line. An isochron excluding this sample gives an age of 4115 ± 100 Ma (MSWD = 4.8) with an initial ϵNd value of $+1.9 \pm 0.3$. The gabbro samples in Fig. 2E define 2 clusters in the isochron diagram and hence might represent 2 distinct groups of gabbros. However only fine grained gabbros displaying the same texture and collected along 2 large continuous sill bodies (35–130 m in width) that can be traced continuously in the field over 1.5 km, were selected for this isochron. T_{DM} values for the central gabbro show less variation with the majority of the samples having T_{DM} values between 3.9 Ga and 4.1 Ga (Fig. 3B).

4.1.3. NGB felsic rocks

A new series of felsic rocks from the NGB were analyzed for their ^{147}Sm – ^{143}Nd isotopic composition. These include samples from the 3.6 Ga tonalite surrounding the NGB, the thin bands of 3.8 Ga intruding trondhjemite, and the 2.7 Ga pegmatites (Table 1). Tonalite samples and the trondhjemitic band sample show a narrow range of $^{147}\text{Sm}/^{144}\text{Nd}$ ratios from 0.1009 to 0.0891 and $^{143}\text{Nd}/^{144}\text{Nd}$ ranging from 0.510199 to 0.509932. The Neoproterozoic pegmatite sample has a slightly higher $^{147}\text{Sm}/^{144}\text{Nd}$ ratio of 0.1260 and a $^{143}\text{Nd}/^{144}\text{Nd}$ ratio of 0.510738. These values are within the range of isotopic compositions previously reported by O’Neil et al. (2008) and David et al. (2009) for the Nuvvuagittuq felsic rocks. The range in Sm/Nd ratios for the tonalities analyzed in this study is too narrow to produce a precise isochron, however, the combined tonalite data from this study, data from O’Neil et al. (2008) and data from David et al. (2009), yields an isochron with an age of 3575 ± 450 Ma (Fig. 2F) with an initial ϵNd value of -2.9 ± 0.4 . This isochron is obtained after rejection of 3 samples with higher Sm/Nd ratios that clearly fall off the main trend for the tonalities. Despite the large error due to the small range in Sm/Nd ratios, this age is in agreement with the U–Pb zircon age of 3661 ± 4 Ma for the Nuvvuagittuq tonalities obtained by David et al. (2009). The Nuvvuagittuq tonalities also have T_{DM} values systematically older than their crystallization age ranging between 3.8 Ga and 3.9 Ga, with 2 samples from O’Neil et al. (2008) yielding T_{DM} of 4.2 and 4.4 Ga (Fig. 3C) that suggest derivation from an older crustal protolith.

4.1.4. Mineral separates

The Sm–Nd isotopic compositions for mineral separates are given in Table 1. Fig. 4A shows the isochron ages obtained from the different mineral separates. All garnet/whole rock tie-lines for

Fig. 2. $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{143}\text{Nd}/^{144}\text{Nd}$ isochron diagrams for (A) All NGB Ujaraaluk and cogenetic ultramafic rocks, (B) the high-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, (C) the depleted low-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, (D) the enriched low-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, (E) the central gabbro sills and (F) the tonalites. Symbols: open symbols, high-Ti Ujaraaluk unit and Type-1 ultramafic; gray symbols, depleted low-Ti Ujaraaluk unit and Type-2 ultramafic; black symbols, enriched low-Ti Ujaraaluk unit and Type-3 ultramafic; vertical diamond, garnet-free Ujaraaluk; horizontal diamond, garnet-bearing Ujaraaluk; triangle, cordierite-anthophyllite Ujaraaluk; circle, ultramafic; gray pluses, gabbro; open square, tonalite. Black symbols in Fig. 2E and F are samples not included in the isochron age calculation.

the Ujaraaluk samples (7 garnet/whole samples) yield Neoproterozoic ages ranging from 2537 Ma to 2735 Ma with negative initial ϵNd values ranging from -9.4 to -12.4 , with PC-230 having an initial ϵNd value of -6.5 (Table SD7). An isochron comprising

only garnet from 7 Ujaraaluk samples, including one sample from the lower greenschist metamorphic grade (PC-536 GRT), gives an age of 2619 ± 50 Ma (Fig. 4B) with an initial ϵNd value of -9.3 ± 1.8 . The coarse grained gabbro (PC-085) yields an isochron

Fig. 3. Histograms of T_{DM} values for (A) the Ujaraaluk unit, (B) the gabbros and (C) the tonalites. Values used for Nd model age calculations are present day $^{143}\text{Nd}/^{144}\text{Nd} = 0.51301$ and $^{147}\text{Sm}/^{144}\text{Nd} = 0.2085$.

Fig. 4. (A) Sm-Nd isochron ages for garnet separates and mineral/whole rock tie-lines. Dashed line is the U-Pb age of the intruding pegmatite at 2686 Ma. Solid vertical line is the U-Pb age for zircons from the central gabbros (see Section 4.4). (B) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{143}\text{Nd}/^{144}\text{Nd}$ isochron diagram for all garnet separate samples.

age (hornblende-plagioclase-whole rock) of 2719 ± 100 Ma, but with a positive ϵNd value of $+1.8 \pm 0.5$ because the whole rock gabbro has a near chondritic Sm/Nd ratio. These Neoproterozoic ages generally overlap within error with the age for the intrusion of the Nuvvuagittuq pegmatite reported by David et al. (2009) of 2686 ± 4 Ma, as does the imprecise whole rock Pb-Pb age of 2.4 ± 0.4 Ga for the Ujaraaluk samples measured in O'Neil et al. (2008). PC-276, in contrast, yields a Proterozoic biotite-whole rock isochron age of 1537 Ma.

4.2. Lu-Hf

Four of the garnet separate samples analyzed for Sm-Nd isotopic composition have also been analyzed for their Lu-Hf isotopic composition, along with their whole rock Lu-Hf isotopic composition (Table SD8). ^{176}Lu - ^{176}Hf garnet/whole rock tie-lines for the Ujaraaluk samples give a wide range of Proterozoic ages with, PC-230 and PC-275 yielding ages of 1655 Ma and 1599 Ma respectively, whereas PC-282 and PC-438 give younger ages of 1219 Ma and 1157 Ma respectively.

4.3. ^{142}Nd

The ^{142}Nd isotopic data are presented in Table 1. The $^{142}\text{Nd}/^{144}\text{Nd}$ ratios of the Ujaraaluk rocks show a 26 ppm variation ranging from samples having an excess in ^{142}Nd (up to +8 ppm) to samples having a deficit in ^{142}Nd (up to -18 ppm) relative to the terrestrial standard (Fig. 5). The $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for this entire set of samples correlate with their Sm/Nd ratios. This correlation

Fig. 5. $\mu^{142}\text{Nd}$ values for all NGB samples relative to the terrestrial Nd standard. Vertical gray band shows the 4.5 ppm external error. Samples are sorted in order of Sm/Nd ratios for each different geochemical group/lithology. The different geochemical groups/lithologies are separated by alternating white and gray horizontal zones. Symbols as in Fig. 2; open pluses, trondhjemitic bands; open star, pegmatite.

between the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios and Sm/Nd ratios also is present when considering the 3 different geochemical groups of Ujaraaluk individually. The largest deficits in ^{142}Nd are observed in the enriched low-Ti Ujaraaluk, whereas the sample yielding a $\mu^{142}\text{Nd}$ of +8 is an ultramafic rock from the high-Ti Ujaraaluk group. The central gabbro samples also exhibit a correlation between their $^{142}\text{Nd}/^{144}\text{Nd}$ and their $^{147}\text{Sm}/^{144}\text{Nd}$ ratios, but with a smaller range in $\mu^{142}\text{Nd}$ values from 0 to -8 relative to terrestrial standard. All Nuvvuagittuq felsic rocks analyzed, including the tonalities (-6 to -14 ppm), the trondhjemitic band (-9 ppm) and the pegmatite (-11 ppm) yield deficits in ^{142}Nd relative to the terrestrial standard (Fig. 5). There is, however, no correlation between the $^{142}\text{Nd}/^{144}\text{Nd}$ and the $^{147}\text{Sm}/^{144}\text{Nd}$ ratios for any felsic lithology. The ^{142}Nd isotopic data measured in this study are consistent with the data reported by O'Neil et al. (2008) for every lithology, but expands the range of isotopic compositions exhibiting this correlation. The deficits in ^{142}Nd in rocks from the NGB have been confirmed by measurements of the same samples in an independent lab at ETH Zurich (Roth et al., 2011).

4.4. Zircon U-Pb

Zircons from three central gabbro samples have been analyzed by LA-ICP-MS (Table SD9). The analyzed zircons were relatively

Fig. 6. U-Pb concordia diagram for zircons in the central gabbros. Ellipses are 2σ error. Solid gray ellipses are for $10\ \mu\text{m}$ laser spots normalized to GJ-1 standard and open ellipses are for $5\ \mu\text{m}$ laser spots normalized to Plesovice standard.

rounded in shape and between $30\ \mu\text{m}$ and $10\ \mu\text{m}$ in size with most of them being $\sim 20\ \mu\text{m}$. The most concordant zircons ($n = 31$) yield a $^{207}\text{Pb}/^{206}\text{Pb}$ age of $2691 \pm 13\ \text{Ma}$ (Fig. 6) in agreement with the age of the intrusion of the pegmatite and the metamorphic ages obtained on the mineral separates.

5. Discussion

5.1. Significance of the Ujaraaluk ^{142}Nd isotopic composition

^{146}Sm decays into ^{142}Nd with a half-life of $T_{1/2} = 68\ \text{Ma}$ (Kinoshita et al., 2012). Given this short half life, ^{146}Sm is effectively extinct by $\sim 4.0\ \text{Ga}$, therefore any deviation of the ^{142}Nd isotopic composition from the terrestrial standard has to be produced by fractionation between Sm and Nd that occurred prior to 4.0 Ga. The ^{142}Nd data set for the Nuvvuagittuq rocks has been expanded with 30 samples having a resolvable deficit in ^{142}Nd compared to the terrestrial standard. Most samples with low $^{142}\text{Nd}/^{144}\text{Nd}$ derive from the enriched low-Ti Ujaraaluk group. Within every group of Ujaraaluk, however, the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios correlate with Sm/Nd ratios. Any valid model for the origin of the Ujaraaluk unit needs to account for three main features regarding their ^{142}Nd isotopic composition. First, it must explain the deficit in ^{142}Nd relative to the terrestrial standard. Second, it must account for the 26 ppm range in ^{142}Nd observed in the Ujaraaluk and cogenetic ultramafic sills. Third, it must explain the correlation between the Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for all Ujaraaluk rocks and within each individual geochemical group. Here, we will discuss 3 possible models that could potentially explain the observed ^{142}Nd deficits: (1) Derivation of the NGB rocks in the Eoarchean from an enriched mantle formed in the Hadean, (2) Mixing in the Eoarchean with an Hadean enriched mantle reservoir and (3) Formation of the NGB rocks in the Hadean. We then will evaluate which model best accounts for the ^{142}Nd isotopic composition of the NGB rocks.

5.1.1. Derivation from an Hadean enriched mantle

Variability in ^{142}Nd in relatively young rocks can be inherited from mantle sources whose Sm/Nd ratios were fractionated by differentiation events occurring prior to 4 Ga. A clear example is the presence of a wide range in initial $^{142}\text{Nd}/^{144}\text{Nd}$ in $< 4\ \text{Ga}$ old lunar mare basalts (Rankenburg et al., 2006; Boyet and Carlson, 2007). Most terrestrial rocks have a $\sim 20\ \text{ppm}$ excess in ^{142}Nd compared to ordinary chondrites, which led Boyet and Carlson (2005, 2006)

Fig. 7. $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagram. Symbols as in Fig. 2; green crosses, Isua samples from Rizo et al. (2011) and Bennett et al. (2007); green star, Isua-like depleted reservoir (IDR) isotopic composition with a $^{147}\text{Sm}/^{144}\text{Nd}$ ratio = 0.225 and a $\mu^{142}\text{Nd}$ value of $\sim +9$ relative to terrestrial standard (Rizo et al., 2011; the $^{147}\text{Sm}/^{144}\text{Nd}$ ratio was re-calculated using the ^{146}Sm half-life of 68 Ma); yellow star, possible complementary Isua-like enriched reservoir (IER) with a $\mu^{142}\text{Nd}$ value of ~ -15 ppm relative to terrestrial standard to account for the most negative NGB values and a $^{147}\text{Sm}/^{144}\text{Nd}$ ratio = 0.182, required for an age of differentiation of 4.47 Ga (Rizo et al., 2011). Horizontal black line shows the terrestrial standard value with 4.5 ppm external error gray band. Oblique black line shows the best fit for the Ujaraaluk sample correlation with 4.5 ppm external error being shown by the gray band. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

to propose that the Bulk Silicate Earth either has a superchondritic Sm/Nd ratio or differentiated within 30 Ma of planet formation to form an early depleted mantle. If the bulk Earth is chondritic in Sm/Nd ratio, then the formation of an early depleted, i.e. high Sm/Nd ratio, reservoir having an excess in ^{142}Nd must be coupled with the formation of an early enriched reservoir (EER) that is characterized by a complementary deficit in ^{142}Nd (Boyet and Carlson, 2006). Any rock derived from the EER will carry this deficit in ^{142}Nd independent of its age. Such rocks will not only have a deficit in ^{142}Nd relative to the terrestrial standard, but also relative to ordinary chondrite (i.e. ~ -40 ppm relative to the terrestrial standard). The NGB rocks have ^{142}Nd deficits up to -18 ppm relative to terrestrial standard and thus no deficit relative to ordinary chondrites. Therefore, the NGB rocks cannot be derived directly from the EER.

Positive anomalies in ^{142}Nd are found in amphibolites from Isua in SW Greenland. These ~ 3.8 Ga rocks have an excess in ^{142}Nd (up to $+19$ ppm) compared to terrestrial standards (Rizo et al., 2011; Boyet and Carlson, 2006; Caro et al., 2003, 2006; Bennett et al., 2007). There is no correlation between the $^{147}\text{Sm}/^{143}\text{Nd}$ and the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios in the Isua amphibolites (Fig. 7), consequently, the most likely origin of the excess ^{142}Nd in these rocks is that their mantle source was formed in the Hadean and was depleted in incompatible elements (i.e. high Sm/Nd ratio) (Caro et al., 2006; Bennett et al., 2007; Rizo et al., 2011). This mantle reservoir was later sampled by an Eoarchean crust forming event that produced melts with variable Sm/Nd ratio as a result of magmatic fractionation, but with ^{142}Nd excess inherited from the source. Because ^{146}Sm was extinct by 3.8 Ga, the rocks formed

from these magmas will retain their initially uncorrelated Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios to the present day. An Hadean complementary enriched reservoir to the Isua mantle source would have a deficit in ^{142}Nd relative to the terrestrial standard. Rocks derived from such an enriched reservoir during some later melting event would therefore yield negative anomalies in ^{142}Nd and thus could have similar isotopic compositions to the NGB rocks. However, partial fusion after 4.0 Ga of an enriched mantle with a deficit in ^{142}Nd will produce magmas with deficits in ^{142}Nd that need not correlate with Sm/Nd ratio, as shown by the analogous case of the Isua amphibolites (Fig. 7). In other words, all rocks derived from this source would have the same ^{142}Nd isotopic composition, regardless of their Sm/Nd ratios. Direct post-4.0 Ga derivation from an enriched mantle reservoir formed contemporaneously with the Isua mantle source cannot account for the 26 ppm variation in ^{142}Nd observed in the NGB rocks and more importantly, cannot explain the correlation between the Sm/Nd and the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios characteristic of the Ujaraaluk unit.

5.1.2. Mixing of Hadean enriched and depleted mantle reservoirs

There is always the possibility that a correlated array of Nd isotopic composition and Sm/Nd ratio may represent a mixing line between 2 isotopically distinct reservoirs. The minimum age for the Ujaraaluk unit is constrained by the intrusion of the trondhjemitic bands dated at ~ 3.8 Ga (Cates and Mojzsis, 2007; David et al., 2009). The only way that the Ujaraaluk can have a deficit in ^{142}Nd if they indeed formed at 3.8 Ga, is to involve an Hadean enriched component in their petrogenesis. If the Ujaraaluk unit formed at 3.8 Ga from a “normal” depleted mantle (DM) source, mixing with an early enriched reservoir (EER) would induce a ^{142}Nd deficit and could yield a correlation between Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ if igneous fractionation did not greatly change the Sm/Nd ratios of the mixed rocks (Fig. 8A). In this case, the correlation between the Sm/Nd and the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios would represent a mixing line without any age significance for the Ujaraaluk, at best providing only an approximate age for the time of separation of the EER and the DM. If the Ujaraaluk Sm/Nd vs. ^{142}Nd correlation is a mixing line, the $^{147}\text{Sm}/^{144}\text{Nd}$ ratio of the enriched reservoir must be less than ~ 0.12 , and have a ^{142}Nd deficit of at least ~ -20 ppm relative to terrestrial standard (EER 1 in Fig. 8A). Given that mantle rocks with $^{147}\text{Sm}/^{144}\text{Nd}$ significantly less than 0.12 are uncommon [even the KREEP component of the Moon, a possible analog to an early terrestrial EER, has a $^{147}\text{Sm}/^{144}\text{Nd}$ of ~ 0.168 (Lugmair and Carlson, 1978)], the lowest Sm/Nd ratio end member in the Ujaraaluk would have to be dominated by the enriched end member. One could imagine that the early-formed enriched reservoir might be a strongly LREE enriched Hadean felsic crust, in which case the lowest Sm/Nd ratio end member in the Ujaraaluk would still require more than a 50% by mass contribution from such “crustal contamination” if the mantle-derived end member were from “normal” terrestrial mantle. Given the basaltic major element composition of the low Sm/Nd ratio end of the Ujaraaluk rocks, the compositional characteristics of the Ujaraaluk rocks do not support the possibility that this enriched mixing end member is Hadean felsic crust. Furthermore, if the ^{142}Nd deficits in the Ujaraaluk unit were produced by mixing with an Hadean LREE-enriched reservoir, a correlation between the Nd concentrations and the ^{142}Nd isotopic compositions at the time of mixing (presumably 3.8 Ga) would be expected. However, the $\mu^{142}\text{Nd}$ values of the Nuvvuagittuq rocks show absolutely no correlation with their Nd concentrations for the entire set of data or within the individual Ujaraaluk geochemical groups (Fig. 8B). Moreover, if the ^{142}Nd deficits observed in most NGB lithologies, and the Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation, were produced by mixing between enriched and depleted mantle sources at 3.8 Ga, a positive correlation between Sm/Nd ratio and initial $^{143}\text{Nd}/^{144}\text{Nd}_{(3.8\text{Ga})}$ would be expected that would give a

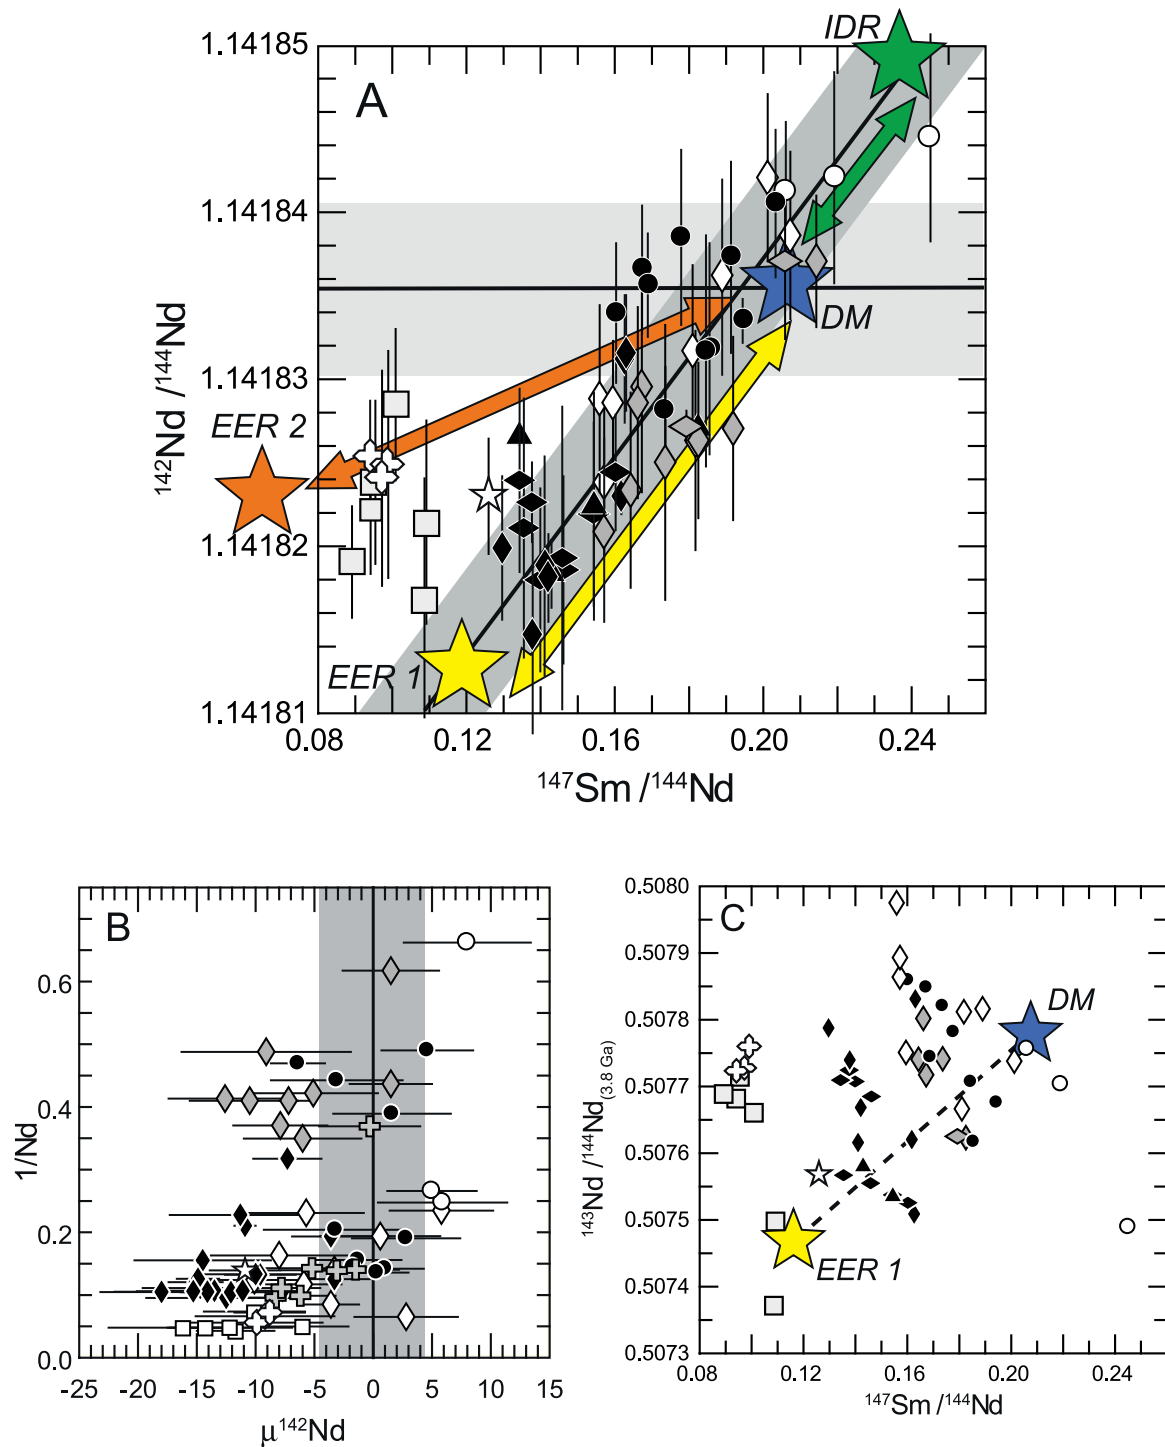

Fig. 8. (A) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagram. Symbols as in Fig. 5; blue star, DM; green star, Isua-like depleted reservoir (IDR) isotopic composition required to account for the superchondritic end of the Ujaraaluk correlation; yellow star, EER1 isotopic composition required to account for the subchondritic end of the Ujaraaluk correlation; orange star, EER2 isotopic composition required to account for the NGB felsic rocks. Horizontal black line shows the terrestrial standard value with 4.5 ppm external error. Oblique black line shows the best fit for the Ujaraaluk samples correlation with 4.5 ppm external error being shown by the gray band. Simple two-component mixing would predict a linear correlation between a low $1/\text{Nd}$ at negative $\mu^{142}\text{Nd}$ enriched source and a high $1/\text{Nd}$, positive $\mu^{142}\text{Nd}$ depleted source. No such correlation is apparent in the data as the different compositional groups primarily all show a similar range in $\mu^{142}\text{Nd}$, offset at different Nd concentrations. (B) Measured $\mu^{142}\text{Nd}$ vs. $1/\text{Nd}$ concentration. (C) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. initial $^{143}\text{Nd}/^{144}\text{Nd}$ calculated at 3.8 Ga. Symbols as in Fig. 5. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

slope with an age somewhere between the time of the mixing event and the formation of the enriched and depleted mantle reservoirs. This would also result in a Sm/Nd vs. $^{143}\text{Nd}/^{144}\text{Nd}_{(\text{today})}$ correlation producing a “fossil” isochron with an age older than 3.8 Ga. A ^{147}Sm – ^{143}Nd isochron diagram constructed for the

Ujaraaluk samples using the $^{143}\text{Nd}/^{144}\text{Nd}$ ratios calculated at 3.8 Ga (Fig. 8C) displays mostly negative slopes within the individual chemical groups of Ujaraaluk, consistent with the <3.8 Ga ^{147}Sm – ^{143}Nd isochron ages calculated for the different chemical groups. One could imagine a positive slope passing through the

midpoints of the negative slopes of the individual chemical units shown in Fig. 8C that could be attributed to formation of the different chemical groups by mixing between Hadean depleted and enriched mantle sources. In this case, however, the negative correlations between the Sm/Nd and $^{143}\text{Nd}/^{144}\text{Nd}_{(3.8\text{ Ga})}$ ratios in the individual chemical groups would have to be attributed to substantial modification of Sm/Nd ratios after 3.8 Ga. However, changes to Sm/Nd ratio caused either by magmatic differentiation at 3.8 Ga, or by metamorphism after 3.8 Ga would not be accompanied by changes in $^{142}\text{Nd}/^{144}\text{Nd}$ because ^{146}Sm was extinct by this time. Consequently, if the lack of a clear positive correlation between Sm/Nd and $^{143}\text{Nd}/^{144}\text{Nd}_{(3.8\text{ Ga})}$ is due to either magmatic or metamorphic modification of Sm/Nd ratio at 3.8 Ga or later, then a similar, or greater, degree of scatter should be observed in the Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ plot, yet this isochron diagram shows a good positive correlation for all Ujaraaluk samples and for each individual chemical group (see Fig. 10).

Although the possibility of mixing between Hadean enriched and depleted sources in the Archean to explain the NGB ^{142}Nd isotopic composition cannot completely be ruled out, another complication if all the NGB rocks formed in the Eoarchean is that the Eoarchean felsic rocks, including the only rocks unequivocally dated at 3.8 Ga (i.e. the trondhjemitic bands), do not fall on the same Sm–Nd array defined by the Ujaraaluk samples (Fig. 8A). If the Ujaraaluk Sm/Nd– ^{142}Nd array reflects simple two-component mixing between enriched and depleted mantle sources at 3.8 Ga, then the offset of the felsic rocks from this line suggests a second enriched source (EER 2 in Fig. 8A) with much lower Sm/Nd ratio at the same $^{142}\text{Nd}/^{144}\text{Nd}$ ratio compared to the enriched source involved in the Ujaraaluk correlation. Moreover, the 2.7 Ga pegmatite would have to acquire its ^{142}Nd deficit by mixing with the same enriched source sampled by the Ujaraaluk (EER 1 in Fig. 8A), but over a billion years later, implying not only alternating sampling of different mixed sources (EER 1 and EER 2) in time but also the survival of these enriched reservoirs within the mantle for at least 1.5 billion years. Alternatively, the offset of the felsic rocks to lower Sm/Nd ratio compared to the Ujaraaluk correlation could reflect the magmatic fractionation of Sm/Nd ratio during the production and differentiation of these felsic rocks at various times post 3.8 Ga. If a similar magmatic fractionation of Sm/Nd ratio in the Ujaraaluk occurred, as is suggested by the trace element characteristics of the Ujaraaluk (O’Neil et al., 2011a), then the preservation of a correlation between Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratio in a two-component mixture of enriched and depleted mantle sources is surprising if these rocks formed after ^{146}Sm became extinct. At the high Sm/Nd ratio end of the Ujaraaluk correlation, the slight excess in ^{142}Nd observed in some NGB ultramafic rocks would require the involvement of an early Isua-like depleted reservoir to produce $\mu^{142}\text{Nd}$ values as high as +8 (Fig. 8A). Therefore, a mixing model to account for the Sm–Nd systematics of all NGB lithologies would require at least 3 distinct sources including an early Isua-like depleted reservoir and 2 early enriched reservoirs. While such complicated mixing scenarios cannot be ruled out unequivocally, we consider them geologically unlikely.

All three Ujaraaluk geochemical groups follow the exact same Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation (Fig. 10A). O’Neil et al. (2011a) showed that these Ujaraaluk groups have distinct major and trace element compositions suggesting that they were formed in different geological settings and derived from mantle sources with different geochemical compositions. The high-Ti Ujaraaluk unit is consistent with derivation from an undepleted mantle source and fractionation under relatively dry conditions, while both low-Ti Ujaraaluk units appear to be derived from a mantle source that had experienced enrichment of highly incompatible elements followed by magmatic fractionation under elevated water pressures. Prior to the source incompatible element enrichment, the

mantle source of the depleted low-Ti Ujaraaluk unit appears to have been a refractory mantle (e.g. subchondritic Sm/Yb ratios) whereas the enriched low-Ti Ujaraaluk shows flat middle to heavy REE patterns consistent with an initially undepleted mantle source. Given that the three Ujaraaluk groups have distinct major and trace element compositions that imply they were produced from geochemically distinct mantle sources, fractionated under different conditions at low pressure, and possibly were produced in different geological settings, we consider it highly unlikely that the Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation represents a mixing line where all three Ujaraaluk groups could have formed from the same isotopic end-members, producing a single correlation for the three compositionally distinct groups. Moreover, even a complex mixing history between depleted and enriched reservoirs cannot produce the isotopic relationship observed between the Ujaraaluk and their cogenetic ultramafic sills. As shown in O’Neil et al. (2011a), the sills share the same Al–Ti–Zr trends that define the 3 Ujaraaluk compositional groups with compositions controlled primarily by olivine fractionation (Fig. 9A). These compositional features suggest that the ultramafic rocks are cumulate bodies formed by the Ujaraaluk parental magmas. The magmatic accumulation of olivine, and possibly orthopyroxene, will produce cumulates with high Sm/Nd ratios relative to the liquid. If the magmatic accumulation occurred after 4.0 Ga, the ultramafic cumulates would have high Sm/Nd ratios, but retain the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios of the Ujaraaluk parental magmas because ^{146}Sm is no longer extant to produce a change in ^{142}Nd abundance. High Sm/Nd ratio cumulates produced after 4.0 Ga would thus be expected to lie to the high Sm/Nd ratio side of the Ujaraaluk Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ array for the same reason that the felsic rocks lie to the low Sm/Nd side of the array if they are partial melts or fractionated liquids from some parental rock/magma lying on the Ujaraaluk array. The same would be true if the ultramafic rocks are interpreted as restites from partial melting that produced the Ujaraaluk parental magmas. If this magma–restite relationship was established at 3.8 Ga, the Ujaraaluk ultramafic rocks would today be offset to high Sm/Nd ratio from the Sm/Nd– $^{142}\text{Nd}/^{144}\text{Nd}$ correlation shown by the Ujaraaluk mafic rocks. If the ultramafic rocks formed before 4.0 Ga, however, while ^{146}Sm was still actively decaying, their high Sm/Nd ratios would lead to high $^{142}\text{Nd}/^{144}\text{Nd}$ ratios compared to the Ujaraaluk magmas. The Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation between the Ujaraaluk and their cogenetic ultramafic cumulates observed in each of the geochemical groups (Fig. 9B) can only be explained if the mineral fractionation forming the ultramafic cumulates occurred before 4.0 Ga. The isotopic relationship between the Ujaraaluk and their cogenetic ultramafic sills thus supports an Hadean formation age for the mafic/ultramafic rocks of the NGB.

5.1.3. Formation of the NGB rocks in the Hadean

In the simple case involving no metamorphic disturbance and no initial variation in the isotopic composition of the whole rocks, the correlation between Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios in the Ujaraaluk would represent an isochron dating the time of the igneous event that formed these rocks. The Sm– ^{142}Nd isochron passes, within error, through the DM isotopic composition consistent with the derivation of the Ujaraaluk from “normal” depleted mantle and does not require the involvement of any “missing” enriched reservoirs or Isua-like depleted reservoirs. The decay of ^{146}Sm in rocks with Sm/Nd ratios higher than the depleted mantle, primarily the cumulate ultramafic rocks, led to $^{142}\text{Nd}/^{144}\text{Nd}$ ratios higher than the modern depleted mantle whereas those with low Sm/Nd ratio ended up with a deficit in ^{142}Nd compared to depleted mantle. While O’Neil et al. (2011a) interpreted the relationship of mafic to ultramafic Ujaraaluk rocks as parental magma to cumulate, the ultramafic rocks also could be proposed to represent the residues of the partial melting that produced the

Fig. 9. (A) Pearce-type plot of $(\text{Fe} + \text{Mg})/\text{Al}$ vs. Si/Al and (B) Mg vs. Ca (cation units) diagram for the ultramafic samples illustrating the primary control of olivine fractionation. (C) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagrams for the enriched low-Ti Ujaraaluk and (D) high-Ti Ujaraaluk. Symbols as in Fig. 2. Green areas highlight the ultramafic samples. Blue areas highlight the compositionally associated Ujaraaluk unit samples. Gray bands show the 4.5 ppm external error on the terrestrial standard value and the best fit lines. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

mafic Ujaraaluk magmas. If this hypothetical relationship were established by melting at 3.8 Ga, both magma and restite would today have the same $^{142}\text{Nd}/^{144}\text{Nd}$ because there would be no ^{146}Sm extant to increase the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios in the high Sm/Nd ratio ultramafic rocks. There is no petrological or geochemical evidence supporting the idea that each of the Ujaraaluk groups is composed of a series of restites and melts. On the contrary, the major and trace element compositional variations of the mafic rocks from the three groups of Ujaraaluk are consistent with fractional crystallization from distinct parental magmas, whereas the composition of the ultramafic samples is consistent with them being cogenetic cumulates to the different mafic parental magmas (O'Neil et al., 2011a). Therefore, the compositional variations of the Ujaraaluk unit and the ultramafic rocks, as well as the Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ ratio correlation are interpreted to be primary features acquired during the emplacement and crystallization of the Ujaraaluk unit.

The ^{146}Sm - ^{142}Nd isochron for all Ujaraaluk samples and cogenetic sills corresponds to an age of 4388^{+15}_{-17} Ma (Fig. 10A) with an initial $\mu^{142}\text{Nd}$ value of $+4.7 \pm 2.0$ overlapping with the "normal" DM. Fitting all the Ujaraaluk mafic samples only, the isochron gives the same age of 4388^{+18}_{-24} Ma. Isochrons fit individually to each of the different compositional groups in the Ujaraaluk (Fig. 10B-D)

give ages of 4363^{+21}_{-26} Ma, 4374^{+26}_{-35} Ma and 4409^{+23}_{-29} Ma for the high-Ti, depleted low-Ti, and enriched low-Ti groups respectively. Further support for an Hadean age for the Ujaraaluk unit is provided by the central intruding gabbro whose ^{146}Sm - ^{142}Nd systematics yield an age of 4313^{+41}_{-69} Ma (Fig. 10E). The Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation for the central gabbros is however not well-defined due to the limited spread in Sm/Nd ratios and the consequent limited variation in $^{142}\text{Nd}/^{144}\text{Nd}$. Nevertheless, both the ^{146}Sm - ^{142}Nd and ^{147}Sm - ^{143}Nd systematics for the gabbros suggest an Hadean age of emplacement, providing a minimum age for Ujaraaluk unit. The ^{146}Sm - ^{142}Nd isochron for these gabbros also passes through the DM with an initial $\mu^{142}\text{Nd}$ value of $+0.1 \pm 3.1$.

5.2. Consequences of metamorphic disturbance

If the NGB rocks were not affected by later metamorphism, then the ^{147}Sm - ^{143}Nd and ^{146}Sm - ^{142}Nd data should provide concordant ages. The NGB has been extensively affected by metamorphism in the Neoproterozoic, however, as indicated by the numerous Sm - Nd ages on metamorphic minerals in the Ujaraaluk unit and intruding gabbro ranging between 2537 Ma and 2735 Ma (Fig. 4, Table SD6). These ages overlap the U-Pb zircon age of the intruding pegmatite, the U-Pb ages obtained on metamorphic

Fig. 10. $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ isochron diagrams for (A) All NGB Ujaraaluk and cogenetic ultramafic rocks, (B) the high-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, (C) the depleted low-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, (D) the enriched low-Ti Ujaraaluk geochemical group and cogenetic ultramafic rocks, and (E) the central gabbro sills. Gray bands show the 4.5 ppm external error on the terrestrial standard value and the best fit lines. Symbols as in Fig. 2; blue star, DM. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

zircon, rutile and monazite in the Ujaraaluk unit (O'Neil et al., 2011b; Darling et al., 2012) and the central gabbros (Fig. 6), as well as the Pb-Pb age defined by whole rock samples of the Ujaraaluk (O'Neil et al., 2008). These results suggest that the peak of the metamorphism occurred at ~ 2.7 Ga, contemporaneous with the

emplacement of the Boizard suite (Simard et al., 2003) of heterogeneous tonalites surrounding the NGB supracrustal rocks and the 3.6 Ga NGB tonalite. Post-magmatic disturbance is also supported by younger Proterozoic Lu-Hf ages obtained in the same garnet dissolutions that provided Neoproterozoic Sm-Nd ages.

The long-lived ^{147}Sm - ^{143}Nd isotopic system can be affected by younger thermal events even at the whole rock scale. The data presented here show clearly that the ^{147}Sm - ^{143}Nd system in the NBG samples has been affected by the Neoproterozoic metamorphism. The ^{147}Sm - ^{143}Nd systematics for the different compositional groups of Ujaraaluk give ages between 3734 Ma and 2517 Ma with large errors, significant scatter, and a wide range of initial ϵNd values. The best example of this is the isochron for the enriched low-Ti Ujaraaluk that yields an age of 3734 Ma, but is clearly composed of 2 different groups of samples with 2 different slopes, both of which give Neoproterozoic ages (Fig. 2D). Small metamorphically induced changes to Sm/Nd ratios at 2.7 Ga will have significant effect on the evolution of ^{143}Nd as ^{147}Sm continues to decay to the present day. The same is not true for the ^{146}Sm - ^{142}Nd system, however, because ^{146}Sm was long extinct by 2.7 Ga. Thus, late metamorphic changes to the Sm-Nd system will affect the ^{147}Sm - ^{143}Nd and ^{146}Sm - ^{142}Nd results differently. The only way to change the $^{142}\text{Nd}/^{144}\text{Nd}$ ratio after ^{146}Sm has become extinct is to involve mixing with a fluid/melt having a different ^{142}Nd isotopic composition. Changes in Sm/Nd ratio after ^{146}Sm is gone will not affect the ^{142}Nd isotopic composition, but will affect the slope of a Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlation, which we show below will have only minimal effect on the ^{146}Sm - ^{142}Nd age obtained.

Fig. 11 shows the effects of a complex metamorphic history on the ^{147}Sm - ^{143}Nd system and the robustness of the ^{146}Sm - ^{142}Nd system. Here we model two scenarios for a 2.7 Ga disturbance in 4.4 Ga rocks and examine the relative effects on both long-lived and short-lived Sm-Nd isotopic systems. The circles in Fig. 11 represent two undisturbed 4.4 Ga Ujaraaluk rocks, a low Sm/Nd rock (U1, U2, U3) and a high Sm/Nd rock (U4, U5, U6), at three different times, from $t = 0$, or 4.4 Ga ago (U1 and U4) to today (U3 and U6). In the first scenario (Fig. 11A), at 2.7 Ga (or 1.7 Ga after $t = 0$), the undisturbed rocks (U2 and U5) are affected by a thermal event and partial melting, producing the ~ 2.7 Ga pegmatites (yellow stars). The analyzed pegmatite sample has a deficit in ^{142}Nd despite the fact that it was produced after 4.0 Ga. Thus the most likely source of the pegmatites is a rock that already contained a ^{142}Nd deficit, such as the Ujaraaluk unit. Melting of the Ujaraaluk unit at 2.7 Ga produces restites with higher Sm/Nd ratios (R1 and R3) and mixing between the pegmatitic liquid and the Ujaraaluk also produces rocks with lower Sm/Nd ratios (M1 and M3). In this case, the two hypothetical Ujaraaluk starting samples are subjected to the same melting scenario and produce their own pegmatitic liquids having the same isotopic composition as their respective parent rocks at the time of melting. The restites and mixed rocks evolve to give ^{147}Sm - ^{143}Nd isochron ages of 2.7 Ga (M2-U3-R2 and M4-U6-R4). Sm/Nd ratios for the restites were calculated using batch melting equations. The composition of the pegmatite (sample R18) was used as the liquid composition whereas the composition of Ujaraaluk sample PC-129 was used as the original unmelted composition of the low Sm/Nd rock (U2) as it falls close to the ^{142}Nd isochron in Fig. 10A and has the same $^{142}\text{Nd}/^{144}\text{Nd}$ ratio as the pegmatite. The variation in Sm/Nd ratio obtained for the low Sm/Nd restite (R1) was used to calculate the Sm/Nd ratio of the high Sm/Nd restite (R3). If the restites are produced from 15% melt extraction of both Ujaraaluk rocks, and the mixed rocks are formed from 30% mixing with the pegmatite, this would translate today to a 5% increase in Sm/Nd for the restite (U6-R4) and 6% decrease in Sm/Nd for the mixed rock (U3-M2). Increasing the Sm/Nd ratio of the high Sm/Nd rocks while decreasing the Sm/Nd ratio of the low Sm/Nd rock will have the largest effect on the ^{142}Nd isochron age. However, the age of the ^{142}Nd isochron only decreases from 4.4 Ga to 4.37 Ga (M2-R4 in Fig. 11C). Different degrees of melting lead to different Sm/Nd ratios but the effect on the ^{142}Nd isochron remains small. Using 5% and 25% melting for the low Sm/Nd rock (R5) and the high Sm/Nd rock (R7)

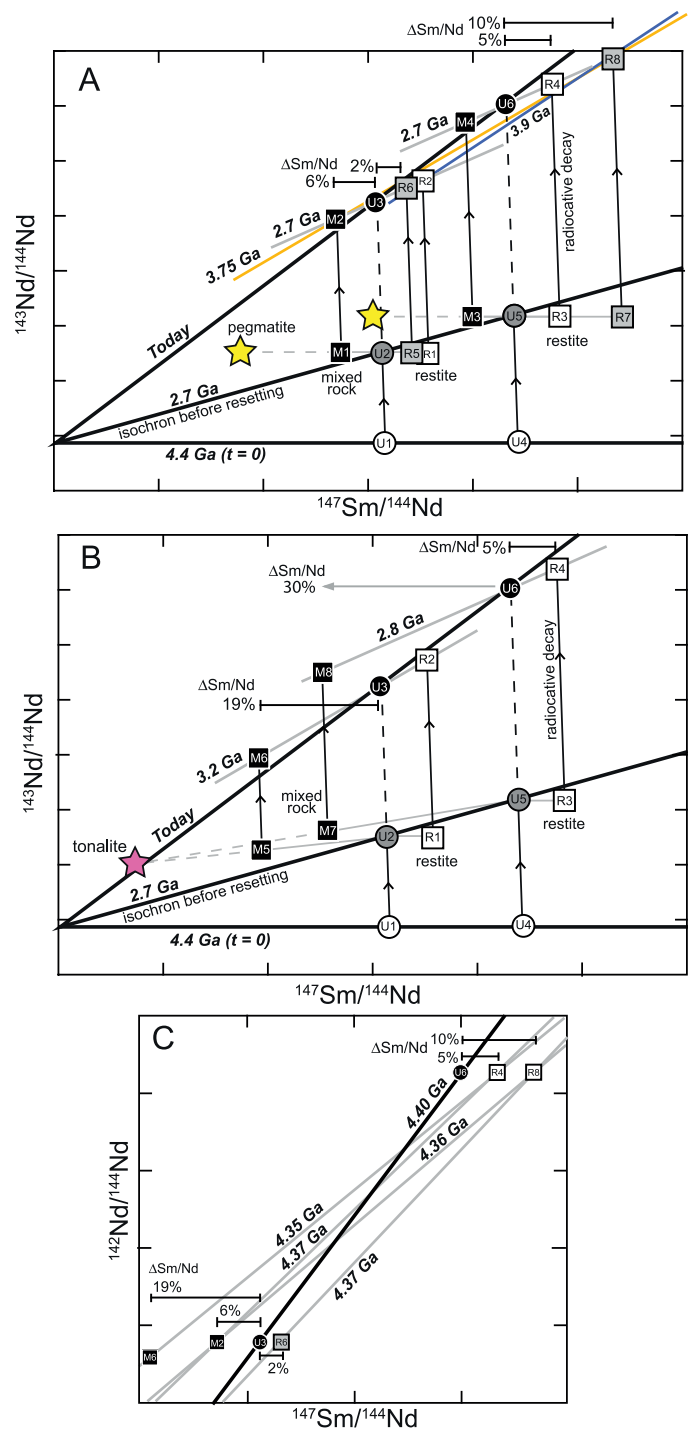

Fig. 11. (A) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{143}\text{Nd}/^{144}\text{Nd}$ diagram showing the effect of a 2.7 Ga isotopic disturbance after partial melting of the Ujaraaluk unit and mixing with a pegmatitic liquid. (B) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{143}\text{Nd}/^{144}\text{Nd}$ diagram showing the effect of a 2.7 Ga isotopic disturbance after partial melting of the Ujaraaluk unit and mixing with a 3.66 Ga tonalitic liquid. (C) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagram showing the effect of the different Sm/Nd variations illustrated in (A) and (B) on the short-lived isotopic system. Symbols: circles, undisturbed Ujaraaluk; R1–R8 squares, restites; M1–M8 squares, mixed rocks, yellow star, pegmatitic liquid; pink star, tonalitic liquid. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

respectively, the ^{143}Nd isochron for the restites yields an age of 3.9 Ga (R6–R8), while the ^{142}Nd isochron age is lowered to 4.37 Ga. A ^{143}Nd isochron passing through the high Sm/Nd restite and the low Sm/Nd mix rock (M2–R8) gives an age of 3.75 Ga, while the ^{142}Nd age decreases to 4.36 Ga.

The second scenario (Fig. 11B) involves partial melting of the Ujaraaluk at 2.7 Ga producing the same restites as in Fig. 11A (R1, R3) but the mixed rocks are formed by mixing between the undisturbed rocks and an enriched tonalite (M5, M7). The tonalite isotopic composition used for the model is in the middle of the range of isotopic compositions measured for the Nuvvuagittuq tonalities. This tonalite has a deficit in ^{142}Nd and therefore will also affect the ^{142}Nd isotopic composition of the mixed rock. A mixture with 30% tonalitic melt produces ^{143}Nd isochrons ranging from 2.8 Ga to 3.4 Ga while the age of the ^{142}Nd isochron goes from 4.4 Ga to 4.36 Ga. The ^{142}Nd isochron is calculated using the high Sm/Nd restite and the low Sm/Nd mix rock (M6-R4) in order to lower the slope of the isochron. Mixing involving more tonalite will have a more important effect on the ages. A mixture with 50% tonalite (Fig. 11B) produces ^{143}Nd isochrons ranging from 3.2 Ga (M6-U3-R2) to 2.8 Ga (M8-U6-R4). This degree of mixing with a tonalite would result in a composition that deviates substantially from the mafic compositions of the Ujaraaluk rocks. Even this high extent of tonalite “contamination”, however, only lowers the ^{142}Nd isochron age to 4.35 Ga (M6-R4 in Fig. 11C). Although there is little evidence that the 3.6 Ga tonalite mixed with the Ujaraaluk at 2.7 Ga, the Ujaraaluk is enclosed by the tonalite at the time of the peak metamorphism and the tonalite represents an obvious potential contaminant. Despite the fact that this tonalitic contaminant would significantly disturb the ^{147}Sm - ^{143}Nd systematics of the Ujaraaluk rocks, the ^{142}Nd ages are relatively unaffected, reinforcing the robustness of the short-lived isotopic system even if the long-lived system is partially reset.

A few Nuvvuagittuq samples show evidence of strong isotopic disturbance consistent with the most extreme cases illustrated in Fig. 11. Two high-Ti Ujaraaluk (PC-058, PC-451) and one depleted low-Ti Ujaraaluk (PC-214) samples lie well off of the Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlations defined by the remaining samples. These samples are interpreted as being strongly disturbed. Samples PC-058 and PC-451 exhibit LREE-enriched profiles strikingly different from the rest of the high-Ti Ujaraaluk samples (Fig. 12A). They also have higher Nd concentrations consistent with them being affected by LREE-enriched fluids during post-magmatic alteration or metamorphism. Both PC-058 and PC-451 fall to the low Sm/Nd side of the ^{146}Sm - ^{142}Nd isochron (Fig. 12A). Though their Sm/Nd ratios are lower than other high-Ti Ujaraaluk samples, their ^{142}Nd isotopic compositions are similar to the least affected high-Ti Ujaraaluk samples with flat REE profiles. Ujaraaluk sample PC-058 exhibits the most extreme offset from the Sm/Nd- ^{142}Nd correlation defined by the majority of the Ujaraaluk samples. The composition of this sample can be reproduced by a disturbance similar to the scenario involving 50% mixing with a tonalitic melt (Fig. 11B). Its strong LREE-enriched profile can be reproduced by 50% mixing of an undisturbed high-Ti Ujaraaluk and a Nuvvuagittuq tonalite (Fig. 12B). A 50% mixture of a high Sm/Nd rock and a tonalite produces a 30% change in Sm/Nd (U6-M8), consistent with the difference in Sm/Nd between PC-058 and an undisturbed sample falling on the ^{142}Nd isochron (35% variation; Fig. 11B). PC-214 is offset to the high Sm/Nd side of the main Ujaraaluk Sm/Nd- ^{142}Nd correlation (Fig. 12A). This sample is an orthopyroxene-rich layer within an ultramafic sill (cogenetic with the depleted low-Ti Ujaraaluk) that exhibits a metamorphic texture with $\sim 120^\circ$ grain boundaries and has a strongly depleted REE profile (Fig. 12A). Formation of a metamorphic orthopyroxenite after 4 Ga will increase the Sm/Nd ratio without affecting the $^{142}\text{Nd}/^{144}\text{Nd}$ ratio. Fig. 12A shows that this sample has been horizontally shifted to the high Sm/Nd side of the Ujaraaluk array with a ^{142}Nd isotopic composition that remained in the same range as the other ultramafic sill values. A ^{147}Sm - ^{143}Nd isochron including ultramafic samples, PC-214 and other pyroxene layers within the same sill yields an age of 2763 Ma (Fig. SD5) supporting the fact that the orthopyroxene layers were formed

Fig. 12. (A) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagram showing the effect of post-4.0 Ga disturbances on some NGB samples. Oblique black line shows the best fit line of Fig. 10A. Gray bands show the 4.5 ppm external error on the terrestrial standard value and the best fit line. Inset diagram shows the REE profiles of the most disturbed Ujaraaluk samples compared to their respective geochemical groups. (B) REE profiles for a Ujaraaluk sample, a tonalite sample, PC-058 (most disturbed sample) along with the composition of 50% mix between the Ujaraaluk and the tonalite. Chondritic normalization values are from Sun and McDonough (1989).

during the Neoproterozoic metamorphism. These three strongly disturbed samples (PC-058, PC-451 and PC-214) fall significantly off their respective $^{147}\text{Sm}/^{143}\text{Nd}$ and ^{146}Sm - ^{142}Nd isochrons and have been considered as outliers and excluded from both the ^{143}Nd and ^{142}Nd age calculations.

In summary, although metamorphism has disturbed the long-lived ^{147}Sm - ^{143}Nd isotopic system in the Ujaraaluk, the effects on the short-lived ^{146}Sm - ^{142}Nd system are not significant. In contrast, the central gabbro sills yield ^{143}Nd and ^{142}Nd isochrons with Hadean ages between 4.1 and 4.3 Ga, suggesting that the ^{143}Nd isotopic system has not been reset to the same extent in the gabbro sills as it has in the Ujaraaluk unit. This may reflect their different lithology. The Ujaraaluk unit is interpreted to be a hydrothermally altered pyroclastic volcanic deposit (O’Neil et al., 2011a), whereas the gabbro sills are massive intrusions that are perhaps more resistant to disturbance by metamorphic fluids/melts. The magnitude of metamorphic disturbance that would turn 4.4 Ga ^{147}Sm - ^{143}Nd ages into the scatter of younger, 3.8–2.7 Ga, ages seen in the various compositional groups of the Ujaraaluk would reduce the ^{146}Sm - ^{142}Nd ages by only of order 50 Ma or less. Thus, while there is no escaping the conclusion that Archean metamorphism has disturbed the Sm-Nd geochronometer in the Ujaraaluk rocks, the discordance between the ^{147}Sm - ^{143}Nd and ^{146}Sm - ^{142}Nd results does not necessarily imply that the ^{146}Sm - ^{142}Nd ages are significantly inaccurate. In fact, in our opinion, the types of metamorphic disturbance modeled in Fig. 11 provide a simpler and more

geologically plausible explanation to the discordant ^{147}Sm – ^{143}Nd and ^{146}Sm – ^{142}Nd ages than do the complicated source mixing models considered in Section 5.1.2. We suggest that the discordance between ^{143}Nd and ^{142}Nd ages provides additional support for our conclusion that the Ujaraaluk rocks formed by partial melting of “normal” depleted mantle in the Hadean, rather than by Eoarchean melting of multiple Hadean mantle sources followed by some complicated mixing/fractionation scenario that would obliterate the Hadean ages from the ^{147}Sm – ^{143}Nd system, but preserve them in ^{146}Sm – ^{142}Nd .

5.3. Origin of the NGB felsic rocks

The Nuvvuagittuq felsic rocks include the 3.8 Ga trondhjemitic bands, the 3.6 Ga tonalites and the 2.7 Ga pegmatites, all Archean in age. Despite the fact that they formed after the extinction of ^{146}Sm , most Nuvvuagittuq felsic rocks have a resolvable deficit in ^{142}Nd (Fig. 5). Negative ^{142}Nd anomalies in Archean rocks indicate that their precursor had a deficit in ^{142}Nd at the time of their formation. The obvious candidates for precursors for the Nuvvuagittuq felsic rocks are the mafic basement rocks of the Ujaraaluk unit. Adam et al. (2011) conducted melting experiments on samples of the Ujaraaluk unit and obtained partial melts that match the compositions of the Nuvvuagittuq tonalites. In the field, enclaves a few meters wide by tens of meters long of mafic amphibolites are observed within the tonalite. The size and number of these mafic enclaves in the tonalite increase as the contact between the tonalite and the Nuvvuagittuq belt is approached and seams of tonalite occur in the mafic lithologies adjacent to the tonalite contact.

All Nuvvuagittuq felsic rocks plot to the low Sm/Nd ratio side of the ^{142}Nd isochron defined by the Ujaraaluk. Partial melting in the Archean of any mafic Ujaraaluk composition will produce a felsic magma with a lower Sm/Nd ratio but with the same $^{142}\text{Nd}/^{144}\text{Nd}$ ratio as their parent rock. The Nuvvuagittuq tonalities yield $\mu^{142}\text{Nd}$ values ranging from -6 to -16 ppm with no correlation between their Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios (Fig. 13) consistent with their derivation from the melting of the mafic Ujaraaluk unit post-4.0 Ga. The Ujaraaluk unit exhibits a wide range of ^{142}Nd isotopic

Fig. 13. $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ diagram showing the effect of post-4.0 Ga partial melting of mafic Ujaraaluk to produce the NGB felsic rocks. Gray bands show the 4.5 ppm external error on the terrestrial standard value and the best fit line. Symbols as in Fig. 5.

compositions, thus partial melting of Ujaraaluk rocks would produce tonalites spanning the same range in $^{142}\text{Nd}/^{144}\text{Nd}$, but with lower Sm/Nd ratios which causes the tonalites to be displaced to the left of the Ujaraaluk ^{146}Sm – ^{142}Nd isochron. Moreover, a ^{147}Sm – ^{143}Nd isochron for the tonalities yields an age of 3575 Ma, consistent with their U–Pb age, but with an initial ϵNd value of -2.9 . This negative ϵNd value at 3575 Ma indicates a much older, low Sm/Nd ratio, precursor for the tonalite. In fact, the initial ^{143}Nd isotopic composition for the tonalites falls on the isotopic evolution line of a 4.4 Ga mantle-derived mafic precursor (Fig. 14) having an isotopic composition consistent with the Ujaraaluk unit. An Hadean source rock for the tonalites is further supported by their T_{DM} values ranging from 3.8 Ga to 4.4 Ga. The trondhjemitic bands and the pegmatites also have deficits in ^{142}Nd with T_{DM} values ranging from 3.8 Ga to 4.2 Ga. These felsic rocks fall on the low Sm/Nd ratio side of the Ujaraaluk ^{146}Sm – ^{142}Nd isochron (Fig. 13) suggesting that they also may have been formed by the partial melting of the Ujaraaluk unit or the central gabbros during later events.

5.4. Other Eoarchean components in the NGB

Beside the trondhjemitic bands and the tonalites, zircons from rocks interpreted to be detrital sediments by some authors (David et al., 2009; Cates et al., 2011; Darling et al., 2012) have yielded Eoarchean U–Pb ages. These rocks include quartzites with 3.78 Ga zircons (Cates et al., 2011), putative conglomerates with distinct zircon populations with ages of 3.78 Ga, 3.66 Ga, 3.36 Ga and ~ 2.7 Ga (David et al., 2009) and rocks interpreted to be quartz-albite-clinozoisite metasediments with concordant zircon ages ranging from 3630 to 3680 Ma. The NGB, however, has been subjected to a complex thermal history and extensive metasomatism sometimes accompanied by the formation of younger metamorphic/metasomatic zircon as seen in the central gabbro (Fig. 6). Understanding the exact geological context of a given lithology, its position in the NGB stratigraphy, and the origins of the zircons it contains thus is critical to the correct interpretation of the zircon age constraints. The detrital origin of the quartz-rich rocks in the NGB is difficult to conclusively demonstrate due to their intensive deformation and recrystallization. The conglomeratic units consist of 0.5–2 m thick horizons containing rounded quartz clasts in a biotite-bearing matrix. The quartz grains in the clasts have ^{18}O -enriched compositions and the trace sulfides in the clasts yield significant mass-independent S isotope fractionation consistent with a sedimentary origin for the quartz and sulfide grains (Kitayama et al., 2011). ^{18}O -enriched compositions and mass-independent S isotope fractionation only suggest a sedimentary origin for the quartz and sulfide grains contained in the conglomeratic unit, but do not require a detrital origin for the host rock. On the other hand, the homogeneity in clast composition is consistent with a single local source, most likely the prominent silica-formation described in O’Neil et al. (2007) interpreted to be a chemical sediment. Kitayama et al. (2011) interpret the conglomeratic unit as a structural mélange of restricted local lithologies, in agreement with the fact that they seem to occur principally in high strain zones. This would suggest that the zircons in the conglomeratic unit do not place any age constraints on the age of the emplacement of the mafic units of the NGB. The similarity in isotopic compositions between the conglomeratic units and the quartz-rich rock interpreted by Cates et al. (2011) to be a detrital quartzite, and the fact that they both contain zircons of the same age is consistent with a similar process for their formation and a similar source for the quartz and the sulfide. Thus, we consider that the quartz-rich rocks do not put geochronological constraints on the age of emplacement of the Ujaraaluk unit. Moreover, all 3.8 Ga zircon-bearing rocks are found to the south of the NGB within less than 100 m of the contact with the tonalite, often in highly deformed

Fig. 14. $\epsilon^{143}\text{Nd}$ vs. time isotopic evolution diagram. Symbols: green diamond, 4.3 Ga Ujaraluk derived from the DM; orange diamond, 3.8 Ga Ujaraluk derived from the EER; gray plus, central gabbro; open plus, trondhjemitic band; gray square, tonalite; black pentagon, Ujaraluk garnet. Age and $\epsilon^{143}\text{Nd}$ data for the gabbro, the tonalite and the Ujaraluk garnet are from the isochrons of Figs. 2E, F and 4B respectively. Age and $\epsilon^{143}\text{Nd}$ data for the DM-derived Ujaraluk are from the isochron diagram of Fig. 15A. $\epsilon^{143}\text{Nd}$ data for the trondhjemitic band is from the average whole rock isotopic composition of 3 samples (Table 1). The initial $\epsilon^{143}\text{Nd}$ value of ~ -2 for the 3.8 Ga EER-derived Ujaraluk was determined considering a 3.8 Ga EER-derived rock with a $^{147}\text{Sm}/^{144}\text{Nd}$ of 0.16 (average Ujaraluk value) that would give an “apparent” T_{DM} of ~ 4.3 Ga. Gray areas are $^{147}\text{Sm}/^{144}\text{Nd}$ isotopic evolution lines ranging from 0.18 to 0.16 for the gabbro and from 0.17 to 0.15 for the Ujaraluk. Symbols on the time scale are U–Pb ages and yellow stars are Sm/Nd isochron ages. Gray vertical areas represent age intervals for the different metamorphic lithologies. The age interval for the metamorphism is estimated using mineral separates and U–Pb ages for the different metamorphic minerals and associated rocks. The age interval for the tonalite represents the error on the U–Pb age (David et al., 2009). The age interval for the trondhjemitic band represents the age difference between David et al. (2009) and Cates and Mojzsis (2007) data. The age interval for the gabbro represents the mean age and error from the ^{143}Nd and ^{142}Nd isochrons (Figs. 2E and 10E). The age interval for the Ujaraluk unit represents the overlap between the ^{143}Nd and the ^{142}Nd isochron ages (see Fig. 15). Gray horizontal lines are ^{143}Nd isochron ages and errors for the gabbro and Ujaraluk unit. Black horizontal lines are ^{142}Nd isochron ages and errors for the gabbro and Ujaraluk unit. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

and sheared areas. The 3.8 Ga zircons could therefore have been formed during an episode of intense deformation responsible for the formation of shearing and structural *mélange* zones consistent with the characteristics of the conglomeratic units. Although the ~ 3800 Ma intrusions of trondhjemitic bands place a minimum age on the Ujaraluk unit, the Ujaraluk also seems to contain rocks interpreted as metasediments that have 3630–3680 Ma zircon ages (Darling et al., 2012), suggesting deposition on a much older basement. This emphasizes the complex geologic history of the NGB and shows that ages obtained on rare zircon-bearing felsic rocks have to be interpreted with caution in terms of the constraints they provide on the age of the dominant mafic lithologies.

5.5. Proposed time scale for the NGB

In this section, we summarize all geochronological evidence to establish a time scale for the NGB and to constrain its secular evolution (Fig. 14). The minimum age of 3.75–3.82 Ga for the NGB was previously established from U–Pb data on the zircons in the felsic

trondhjemitic bands (Cates and Mojzsis, 2007; David et al., 2009). However, the NGB also is intruded by gabbro sills that yield ^{143}Nd and ^{142}Nd isochron ages at ~ 4.2 Ga which pushes back the minimum age of the belt into the Hadean. The Ujaraluk unit is intruded by the central gabbros and therefore must be older than ~ 4.2 Ga. The only model that adequately explains all aspects of the ^{142}Nd isotopic variation within the comagmatic Ujaraluk and ultramafic sills is the one in which the Ujaraluk unit formed while ^{146}Sm was still actively decaying. Therefore, the correlations between the Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for each of the Ujaraluk compositional groups may represent isochrons dating the formation of the Ujaraluk at ~ 4.4 Ga. The Ujaraluk unit is surrounded by the 3.66 Ga Nuvvuagittuq tonalities that apparently formed by the partial melting of the Hadean mafic Ujaraluk unit from which they inherit their ^{142}Nd deficit (Fig. 13). The initial $\epsilon^{143}\text{Nd}$ value indicated by the ^{147}Sm – ^{143}Nd isochron for tonalites falls on the ^{143}Nd evolution line of the ~ 4.4 Ga Ujaraluk unit (Fig. 14). The trondhjemitic bands also have a ^{142}Nd deficit and may as well have been formed by the partial melting of the Ujaraluk unit.

Fig. 15. (A) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{143}\text{Nd}/^{144}\text{Nd}$ isochron diagram and (B) $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ isochron diagram for the least disturbed Ujaraaluk samples and cogenetic ultramafic rocks. Gray bands show the 4.5 ppm external error on the terrestrial standard value and the best fit line on the $^{147}\text{Sm}/^{144}\text{Nd}$ vs. $^{142}\text{Nd}/^{144}\text{Nd}$ isochron diagram.

However the average initial $\epsilon^{143}\text{Nd}$ value of the 3 trondhjemitic band samples (+0.8) falls closer to the evolution line of the central gabbros suggesting that their source may instead be the 4.2 Ga gabbros with $\mu^{142}\text{Nd}$ values overlapping with the $\mu^{142}\text{Nd}$ values for the trondhjemitic bands (Fig. 14). The NGB was then metamorphosed at ~ 2.7 Ga with the concomitant intrusion of pegmatite and the formation of metamorphic minerals such as garnets, rutiles, zircons and monazites. The isochron for garnet separates gives an initial $\epsilon^{143}\text{Nd}$ value falling on the ^{143}Nd evolution line of the 4.4 Ga Ujaraaluk unit consistent with their crystallization from a parent rock that was an mafic Hadean rock before metamorphism (Fig. 14).

The 2.7 Ga thermal event also affected the long-lived Sm–Nd isotopic system for some of the Ujaraaluk unit resulting in poorly defined isochrons ranging from 3.7 Ga to 2.5 Ga and a wide range in Sm–Nd model ages (Fig. 3A). A population of Ujaraaluk samples, however, has T_{DM} values near 4.3 Ga (10 samples with $4.2\text{ Ga} \leq T_{\text{DM}} \leq 4.4\text{ Ga}$; Fig. 3A). This cluster of samples with Hadean model ages could reflect one of three possibilities: (1) they are derived from a “normal” DM at ~ 4.3 Ga and have suffered little or no later modification of their Sm–Nd systems, (2) they were

derived from an enriched (negative $\epsilon^{143}\text{Nd}$; EER in Fig. 14) source at 3.8 Ga or later, or (3) their Sm/Nd ratios have been metamorphically disturbed, resulting in erroneously old T_{DM} model ages. In case 1, the ^{147}Sm – ^{143}Nd isochron defined by these samples would yield an age of 4.3 Ga with an initial $\epsilon^{143}\text{Nd}$ value of $\sim +0.5$. In both cases 2 and 3, the ^{147}Sm – ^{143}Nd isochron for this group of samples would yield a younger (2.5–3.8 Ga) age with a negative initial $\epsilon^{143}\text{Nd}$ value (Fig. 14). Fig. 15A shows a ^{147}Sm – ^{143}Nd isochron for the sub-population of samples with T_{DM} values between 4.2 Ga and 4.4 Ga. This isochron yields an age of 4272 ± 150 Ma with an initial $\epsilon^{143}\text{Nd}$ value of $+0.4 \pm 0.5$ consistent with derivation from a “normal” DM at ~ 4.3 Ga and not from an enriched missing source at 3.8 Ga. This suggests that this population of Ujaraaluk samples have the least disturbed ^{147}Sm – ^{143}Nd systematics. The ^{146}Sm – ^{142}Nd isochron plotting only these least disturbed samples gives an age of 4403^{+14}_{-17} Ma (Fig. 15B), with very little scatter. As for the initial $\epsilon^{143}\text{Nd}$ value, the initial $\mu^{142}\text{Nd}$ value of $+4.7 \pm 2.5$ for this isochron is consistent with derivation from the DM. Following the reasoning that post-4.0 Ga disturbance affects the Sm/Nd ratio without affecting the $^{142}\text{Nd}/^{144}\text{Nd}$ ratio (i.e. a horizontal shift on the isochron diagram), samples falling further from the ^{142}Nd isochron have the most affected $^{147}\text{Sm}/^{144}\text{Nd}$ and thus the most affected $^{143}\text{Nd}/^{144}\text{Nd}$. In Fig. 15B, one of the least disturbed samples (PC-275) plots further from the isochron than the rest of the data, which we interpret as indicating that it has a slightly disturbed Sm–Nd system. Taking this single sample off the isochrons of Fig. 15, the ^{143}Nd age becomes 4321 ± 160 Ma (MSWD = 6.3), whereas the ^{142}Nd age becomes only 3 million years older (i.e. 4406^{+14}_{-17} Ma; MSWD = 1.0). While this subset of samples admittedly has been highly screened in an effort to identify the most pristine samples, nevertheless, this set of samples has consistent Sm–Nd systematics for both the long-lived and short-lived systems both of which give overlapping Hadean ages. Thus, our best estimate for the age of the Ujaraaluk unit is 4406^{+14}_{-17} Ma, which makes it the oldest vestige of crust preserved on Earth. The age of the Ujaraaluk unit overlaps those of the oldest Jack Hills zircons (Wilde et al., 2001) and the oldest zircons from the Moon (Nemchin et al., 2009), suggesting the intriguing possibility that the Nuvvuagittuq Greenstone Belt may preserve a remnant of the first crust formed on Earth after the giant impact that formed the Moon.

6. Conclusions

The ^{142}Nd data set for the Nuvvuagittuq Greenstone Belt rocks has been increased to more than 70 samples. The range in $^{142}\text{Nd}/^{144}\text{Nd}$ ratios is now 26 ppm (–18 ppm to +8 ppm) and the expanded dataset for the Ujaraaluk rocks and associated ultramafic cumulates continues to show a good correlation between the Sm/Nd and the $^{142}\text{Nd}/^{144}\text{Nd}$ ratios for each compositional group. Although a complex mixing model involving an early depleted reservoir and two never-seen-before early enriched reservoirs conceivably could explain this correlation, such a multiple source mixing model cannot account for several characteristics of the Nuvvuagittuq rocks. (1) The major and trace element compositions of the Ujaraaluk are not consistent with simple mixing between a single depleted and a single enriched reservoir. (2) All the compositionally distinct Ujaraaluk groups follow the exact same Sm/Nd vs. ^{142}Nd correlation. The fact that the composition of these groups indicate their derivation from at least three sources with distinct geochemical features followed by distinct fractional crystallization histories under different conditions makes it unlikely that any simple mixing scenario would simultaneously produce identical Sm/Nd vs. $^{142}\text{Nd}/^{144}\text{Nd}$ correlations in all three groups. (3) In a mixing scenario, a correlation between the ^{142}Nd and ^{143}Nd isotopic compositions with Nd concentration would be expected at the time the mixing occurred, as would “fossil” ^{147}Sm – ^{143}Nd

correlations giving ages older than the presumed mixing event. None of these features are present in the Ujaraaluk isotopic data. (4) A mixing event or a melt-restite relationship in the Eoarchean cannot explain the Sm/Nd vs. ^{142}Nd correlation observed between the mafic Ujaraaluk and their cogenetic ultramafic cumulates. (5) An Eoarchean formation age for the Ujaraaluk cannot be reconciled with the intruding gabbros yielding ^{142}Nd and ^{143}Nd isochrons with Hadean ages.

All these features, however, can be explained by a simple model where the Sm/Nd vs. ^{142}Nd correlation is produced by igneous fractionation of the Sm/Nd ratio at constant Nd isotopic composition at a time when ^{146}Sm was still actively decaying, leading to ^{142}Nd isochron ages of ~ 4.4 Ga. The least disturbed Ujaraaluk samples yield a ^{142}Nd isochron age of 4406^{+14}_{-17} Ma and a ^{143}Nd isochron age of 4321 ± 160 Ma supporting an Hadean age. Intruding gabbros give overlapping ^{143}Nd and ^{142}Nd isochron ages with a mean of 4214 ± 140 Ma providing additional support for an Hadean age for the NGB. Therefore, the ^{147}Sm – ^{143}Nd and ^{146}Sm – ^{142}Nd isotopic compositions in the mafic lithologies of the Nuvvuagittuq Greenstone Belt suggest that it represents the oldest crustal remnant on Earth. Following Hadean formation, the NGB was subjected to a complex structural and metamorphic reworking recording over a billion years of Earth's Archean history. Despite the fact that this metamorphic history has affected the long-lived ^{147}Sm – ^{144}Nd isotopic system, the short-lived ^{146}Sm – ^{142}Nd system has not been significantly affected.

The geological evolution of the NGB can be summarized as follows:

- (1) 4.3–4.4 Ga: Eruption and crystallization of the Ujaraaluk unit and comagmatic ultramafic sills. The Ujaraaluk unit exhibits a transition from basaltic rocks having tholeiitic affinities to basaltic rocks that resemble modern boninites to basaltic/andesitic rocks having calc-alkaline affinities.
- (2) 4.2 Ga: Intrusion of gabbro sills in the central part of the NGB.
- (3) 3.8 Ga: Intrusion of trondhjemitic bands produced by the melting of the mafic lithologies. Possible development of shear zones and sutures composed of recrystallized quartz that locally resembles conglomerate texture.
- (4) 3.66 Ga: Formation of the surrounding NGB tonalites by partial melting of the Hadean mafic lithologies.
- (5) ~ 3.3 Ga: Possible metamorphic event recorded in a small population of zircons (David et al., 2009).
- (6) ~ 2.7 Ga: Extensive metamorphism concomitant with the intrusion of pegmatites, formation of metamorphic minerals including garnet, rutile, monazite and zircon in the Ujaraaluk unit, orthopyroxene in the ultramafic sills and zircons in the gabbro sills.

Despite the fact that the Nuvvuagittuq Greenstone Belt was formed less than 300 million years after the beginning of Earth's accretion, it shares geochemical affinities with numerous younger Archean greenstone belts. This suggests that the geological processes still responsible for forming crust were established very early in the Earth's history. Nevertheless, evidence for the existence of stable crust shortly after the Moon forming impact is becoming more abundant, with the 4.3–4.4 Ga Nuvvuagittuq Ujaraaluk and the 4.4 Ga Jack Hills zircons being contemporaneous with the formation of the lunar crust at 4.36–4.41 Ga (Borg et al., 2011; Nemchin et al., 2009).

Acknowledgements

We are grateful to the people and municipality of Inukjuak for their hospitality. We would like to thank the people of the

Pituvik Landholding Corporation, especially Mike Carroll, Johnny Mina, Minnie Palliser, Simeonie Elyasiapik, Arthur Elyasiapik, Aliva Epoo, Simeonie, Minnie Nowkawalk and Noah Echalook, for their critical logistical support in the field. We acknowledge Mary Horan and Timothy Mock for assistance and support in the chemistry lab and with the mass-spectrometers. We also thank Jean-Luc Devidal for assistance on the Microprobe. We acknowledge Mohadeseh Majnoon and Bill Minarik for providing the pegmatite sample. The present paper greatly benefited from useful scientific discussions with Hanika Rizo, Maud Boyet and Steve Shirey. We also thank Alan Brandon and the editor Peter Cawood for their useful comments on the manuscript. This work was supported by the National Science and Engineering Research Council of Canada [Discovery Grants RGPIN 7977-00 to D.F.], the National Science Foundation [NSF-EAR-0910442 to R.W.C.] and the Carnegie Canada Foundation.
