Did the Soviets Collude?: A Statistical Analysis of Championship Chess 1940-64

By Charles Moul and John V. C. Nye

Washington University in St. Louis

Summer 2006

Abstract

We expand the set of outcomes considered by the tournament literature to include draws and use games from post-war chess tournaments to see whether strategic behavior is important in such scenarios. In particular, we examine whether players from the former Soviet Union acted as a cartel in international tournaments -- intentionally drawing against one another in order to focus effort on non-Soviet opponents -- to maximize the chance of some Soviet winning. Using data from international qualifying tournaments as well as USSR national tournaments, we estimate models to test for collusion. Our results are consistent with Soviet draw-collusion and inconsistent with Soviet competition. Simulations of the period's five premier international competitions (the FIDE Candidates tournaments) suggest that the observed Soviet sweep was a 75%-probability event under collusion but only a 25%-probability event had the Soviet players not colluded.

Did the Soviets Collude?: A Statistical Analysis of Championship Chess 1940-64

By Charles Moul and John V. C. Nye

Washington University in St. Louis

Research into how tournament structure affects effort in athletic competition has
generated many insights into the problems of optimal compensation in labor and management. In
much of this literature, outcomes/output are monotonic functions of effort plus an error term (cf.
Ehrenberg and Bognanno, 1990), match-ups end in either wins or losses, and strategic behavior
by players is accordingly considered unimportant. However, many important economic scenarios
are better characterized by the presence of a third outcome that is analogous to a draw, and the
existence of such a draw outcome introduces the potential for strategic behavior. Because of the
quality of their data, chess tournaments are ideal for the examination of issues stemming from
the possibility of draws. In this paper, we test whether Soviet chess players behaved
strategically, effectively acting as a cartel, in international tournaments following World War II.

"Draws" in life are commonplace, and the presence of a draw strategy complicates the
problem of encouraging effort. For instance, a player may have the choice of more and less
conservative strategies with different chances for a draw. Even if we assume that the expected
value of the outcome of a game between players of unequal strength is the same under all
strategy choices, the likelihood of a draw and the risk of a loss are different depending on the
choices that the players make. In the context of chess, if we consider that tournament chess is not
simply stressful but notoriously tiring (hence explaining the dominance of young players at the
top levels of the game, cf. Elo, 1968 on the effects of age on performance) we hypothesize that
very strong players who wish to collude can improve their performance against other players by

agreeing to early or prearranged draws. Assuming for simplicity that the expected outcome of a game between players of equal strength is half a point each, a peaceful pair of agreed draws produces the same outcome with less effort and risk than taking a win and loss apiece[1].

There is now a well-established literature on the economics of sports. For our purposes the most relevant work has focused on the importance of tournament structure in motivating effort and in providing incentives for good play (see the overview by Szymanski, 2003). In most cases the applications have been to athletic competitions, whether individual (golf or tennis) or team sports (basketball or soccer). There is also a related literature on the problem of collusion and of cheating in sports which overlaps with this work (cf. Duggan and Levitt, 2002).

More recently, Ryvkin (2005) has focused attention on the problem of how tournament design not only motivates effort but can also be structured to reveal the relative strengths of

---

[1] Consider the following hypothetical. Assume that a large automotive company wishes to motivate one of its divisions to innovate by offering a very high reward in the event of a new design success. But, consistent with much of the tournament literature, the company also proposes no reward or even punishment if the proposed design fails. Under certain assumptions, the division would do its best to produce a terrific design but only if outcome is monotonic in effort. On the other hand, suppose the division had two options: A low risk design (the draw option) with little chance of being a "home run" but also little chance of being a failure or a high risk design (the play for the win strategy) with a higher probability of leading to a big success but also a greater chance of serious failure. Depending on the precise conditions, it might actually pay the company to use a less skewed payoff structure if it wants to encourage true innovation. This conjecture and its elaboration are subjects of separate and future research. (For work that treats draws in the context of refinements of the prize structure, see Nalebuff and Stiglitz, 1983).

various players. In this light, the purpose of good tournament design is to maximize the

probability that the result of the tournament will produce outcomes that conform to the "true,"

unobserved relative strengths of the participants. Many discussions of tournament structure have

instead focused on "competitiveness." The latter goal actually values a large number of upsets or

unlikely results – such as seem likely to emerge from multi-round knockout tournaments which

are common in tennis or collegiate sports.

In contrast, the chess community seems to put a very high value on competitions that

accurately "reveal" the true strengths of players. Judging by the history of the world

championship and its biases in favor of the incumbent world champion, there seems to be a

revealed preference for a system that anoints the strongest player as World Champion. Periods

when the official world champion was clearly not the strongest player – as occurred when Garry

Kasparov split from FIDE in the 1990s and created a parallel system for the championship –

have seen a loss of legitimacy for the systems that produced champions not widely viewed as the

dominant players.

For the purposes of econometric analysis, chess has numerous advantages which are not

common in other sports. First, the outcomes are clear and objective: A win, a draw, or a loss.

Moreover, a perfect record of all games is theoretically possible and indeed, is available for

virtually all important championship and high level tournament games of the modern era. Most

important of all is that there exists a rating system which is a precise and accurate reflection of

the performances of players and which is an excellent indicator of the relative strengths of

players. When calculated retroactively, these ratings are the best unbiased estimates of relative

strengths and the differences in ratings correspond to the likelihood that the stronger player will

defeat the weaker (cf. Elo, 1968). These Elo-style ratings have since been applied not only to

some other sports but also to studies of revealed preference rankings in college selection (cf.

Avery, et al. 2004).

The question of Soviet collusion during the period when the USSR dominated the

struggle for the world championship has been one of the long-standing debates in the chess

world. The best-known criticism was aired by Bobby Fischer some weeks after the 1962

Candidates tournament in Curacao in the magazine *Sports Illustrated* in an article entitled, "The

Russians Have Fixed World Chess" (cf. Timman, 2005).[2] In it, he claimed that three of the

Soviet players (Keres, Petrosian, Geller) had agreed to pre-arranged draws amongst themselves

in order to conserve energy and to permit themselves to play to the fullest against the non-Soviet

competitors whilst a fourth player, Korchnoi, was forced to throw games to the others to

minimize the chance of a non-Soviet (probably Fischer) winning the tournament[3]. These

allegations have been hard to confirm and many observers have noted that Fischer performed so

poorly in that tournament that any collusion was unlikely to have been the cause of his defeat.

Nonetheless FIDE, the governing body of the world chess organization, was sufficiently

concerned to modify the system for selecting the challenger for the world championship from

1964 onwards.[4]

---

[2] See also Plisetsky and Voronkov, 2005.

[3] Korchnoi has claimed that the trio of Geller, Keres, and Petrosian had agreed upon a private

arrangement to draw amongst themselves.

[4] Timman book on Curacao (2005) goes into the most detail regarding the games themselves.

The testimony of participants since the fall of the Soviet Union makes it more likely than ever

that some kind of draw agreement was in place. Furthermore, Timman's analysis of the critical

game between Keres and Petrosian probably provides the strongest "smoking gun" as far as

Others have also expressed concerns about the extent of Soviet collusion in the period from 1948 to 1962 when Soviet GMs constituted a plurality of the world's grandmasters and an overwhelming majority of the top dozen players. Samuel Reshevsky – the leading US player before the arrival of Bobby Fischer – raised the possibility of non-sporting considerations due to the presence of large numbers of Soviet GMs in the major tournaments of the 1950s[5]. More recently, the Russian grandmaster David Bronstein has suggested that political pressure was put on players during important candidates tournaments in the 1950s, though observers still disagree about the extent to which outright cheating was involved (cf. Soltis 2002a, Soltis 2002b, and Ree, 2002). Whether or not any specific accusation was accurate, the allegations and claims by eyewitnesses and participants are strong enough to suggest the existence of unethical and unsportsmanlike agreements that were also difficult to restrict or regulate.

Most analyses of the question of Soviet collusion have turned on the evaluation of individual games and the judgment as to whether some were deliberately "lost" or "drawn" in favorable positions. For the most part there has been no systematic analysis of the pattern of

---

prearranged draws are concerned. The two players decided to a draw in a position that was extremely favorable towards Black. Timman (a world class grandmaster and at one time the top player in the Western world) provided a detailed chess analysis of the position and said, "My conclusion is that Fischer was correct in declaring that Petrosian agreed to a draw in a winning position," (Timman, 2005, p. 186). This is especially striking considering that both were tied for first with only 3 rounds to follow.

[5] Chess players have also debated the extent to which the Estonian-Soviet grandmaster, Paul Keres, was coerced into losing the world championship to the more politically acceptable Russian, Mikhail Botvinnik (Kingston, 2001).

wins and draws in the tournaments themselves, though all have noted that there was indeed a large number of draws between the three leading Soviet players in Curacao 1962 (Timman, 2005)[6]. We propose to subject the world championship tournaments of the period from 1946-1964 to statistical analysis to see if anything further can be added to this debate by the use of econometrics.

The Structure and History of the World Championship1948 to 1962

Prior to the Second World War, the World Chess Championship was considered the private property of the world champion. He alone could determine which players could challenge him. Championship matches required the solicitation of private funds for the challenger and the champion and the terms of the match were subject to negotiation. If the champion was dethroned, the new champion would have the right to impose conditions on future challengers. Attempts were made to regulate the championships but for the most part these rules were unenforceable because of the private nature of the title.

The death of the world champion Alekhine in 1946 allowed the professional organization FIDE to seize control of the world championship and regulate future competitions. They instituted formal regulations for awarding official titles of international master (IM) and international grandmaster (IGM or more commonly GM) and imposed a structure on acquisition of the world title. To replace Alekhine, a special quintuple round robin tournament split between the Hague and Moscow was held with five invited players in 1948. The players were Botvinnik, Euwe, Keres, Reshevsky, and Smyslov. Botvinnik emerged as world champion. From that point on, the championships were put on a triennial cycle. The point of the cycle (based upon local

---

[6] Though Korchnoi has maintained that it was a private agreement that excluded him and Tal and that he did not purposely lose a game.

competitions arranged by geographic region) was to select players who would play in a

qualifying tournament called the Interzonal. The top six players would then join participants

other than the champion from the last qualifying cycle (the specific details of qualification and

the exceptions therefrom are not important) in a Candidates Tournament, which was a multiple

(two or four) round-robin, or all-play-all, event. The winner of this tournament was designated

the official Challenger who would then play a 24-game match for the world championship

against the incumbent. Should the incumbent be defeated, he was entitled to a rematch. The

Candidates tournaments were considered to be difficult and grueling affairs in which the physical

stamina of the players could have affected the quality of their play. Hence, the concern about

prearranged draws.

Prearranging draws did not violate any explicit rules, because there was no way to

enforce a rule that restricted such behavior.   Despite its equal lack of enforceability, deliberately

losing a game was more likely to be considered outright fraud. Nonetheless all forms of

prearrangement were viewed as unethical or worse. A group of leading players could

conceivably increase their chances of success by playing conservatively amongst themselves at

first and then if necessary, perhaps even throwing games to whichever member of the group

happened to be "in form" as the tournament progressed. In practice, only the USSR had a

consistently large enough group of players in the FIDE qualifying (Interzonal and Candidates)

tournaments for such a plan to be feasible.

This paper seeks to get at the question of "draw collusion" by comparing the pattern of

wins and draws between Soviet players under championship conditions to their performance

against each other in non-world championship events. The fact that the leading Soviet

grandmasters played each other regularly in the USSR chess championship means that we can

observe how strong Soviet GMs performed in critical tournaments when the world championship was not at stake and when there were no political considerations about losing to foreigners.[7]

The Model

We consider two hypotheses that describe player behavior in chess tournaments. Our null is that individuals choose strategies and exert effort to maximize their own likelihood of winning a particular tournament. We will abstract away from some real-world circumstances and restate this as individuals acting to maximize the probability of winning the game that they are playing.[8] Our alternative hypothesis is that Soviet players act as a cartel in FIDE events, acting within constraints to maximize the probability that some member of the cartel wins the tournament.[9] Soviets in non-FIDE events and non-Soviets in all events, however, act to maximize the probability of winning the game that they are playing.

Within the context of the draw collusion explained above, there are three testable implications of the collusion hypothesis.

1. Games that involve two Soviets, are in FIDE events, and end in draws should end with fewer plays than other games that end in draws.

---

[7] There is of course a growing literature on the identification of various forms of cheating. In the economics of sports, the most commonly cited work in this genre is Duggan and Levitt's work on sumo wrestling (2002). There is also a related literature involving biased judging in sporting events (Zitzewitz, 2006; and Garicano, Palacios-Huerta, and Prendergast 2005).

[8] This simplifying assumption runs counter to the observation that a player with a commanding lead going into the last round of a tournament is much likelier to play for a draw.

[9] One plausible such constraint is that, within the cartel, each player wants to win the tournament. Consequently no player is willing to throw matches to other players in the cartel.

2. Games that involve two Soviets and are in FIDE tournaments should be likelier to end in draws than other games.

3. Soviet players should outperform their ratings in FIDE tournaments when playing a non-Soviet opponent.

We will address the first prediction using a simple regression of ply-counts using the sample of games that end in draws. We test the second and third predictions using an ordered probit in which a game's outcome is determined by White's relative advantage over Black (with a disturbance) and thresholds that can vary across game characteristics.

White's relative advantage over Black will be dependent upon the comparative mastery of the two players. We capture this comparison with the concept of *RatingDif*, White's rating less Black's rating.[10] To explore our third prediction, we would ideally have data on the relative fatigue of the two players, or more plausibly the difference between players' cumulative moves at the start of a game. If draw collusion is important and fatigue-avoidance is a primary mechanism, we expect Soviet players to outperform most visibly toward the end of a tournament and likewise expect that such outperformance will be minimal at the start of a tournament. While we will eventually investigate such fatigue measures, we first consider the concept of *SovietDif* as a cruder measure of this relative advantage. *SovietDif* is the difference of a binary variable denoting whether White is Soviet and the same for Black, taking the values of 1, 0 or -1.

The most obvious issue regarding the threshold against which we compare this relative advantage of White is the inherent advantage of White position in moving first. We correspondingly do not expect these base thresholds to be symmetric and impose no such restriction. We further parameterize these thresholds as potentially depending upon whether a

---

[10] We discuss these ratings in greater detail in our review of the data.

game is part of a FIDE tournament (*FIDE*) and whether both players are Soviets and the game is

part of a FIDE tournament (*BothSov*FIDE*). The former parameter measures the extent to which

all players are likelier to draw (play more conservatively) in FIDE events and the latter

parameter captures the collusion hypothesis's second prediction. Preliminary results indicated

that a symmetry assumption on these margins was benign, and parameters reflect this symmetry

restriction.

Formally, let RAW_{jkt} denote player j's relative advantage as White over player k (Black)

at time t. This relative advantage is dependent upon both observed (*RatingDif* and *SovietDif*) and

unobserved characteristics: $RAW_{jkt} = X_{jkt}\,\beta + \varepsilon_{jkt}$, where $\varepsilon \sim N(0, \sigma^2)$. Thresholds depend only

upon observed characteristics (*FIDE*, *BothSov*FIDE*). Let the winning threshold be denoted

$\gamma^{Win}_{jkt} = \gamma^W + Z_{jkt}\,\gamma$, so that player j wins as White if $RAW_{jkt} > \gamma^{Win}_{jkt}$. The losing threshold is

comparable and denoted as $\gamma^{Lose}_{jkt} = \gamma^L - Z_{jkt}\,\gamma$, so that player j loses as White if $RAW_{jkt} < \gamma^{Lose}_{jkt}$.

Player j then draws as White if $\gamma^{Lose}_{jkt} < RAW_{jkt} < \gamma^{Win}_{jkt}$.[11]

These parameters are only identified up to scale, and we accordingly normalize the

variance of the normal disturbance to $\sigma = 1$. We estimate these parameters using maximum

likelihood.

The Data

Our data were supplied by Jeff Sonas of Chessmetrics.com and include all non-playoff

games of FIDE events and the Soviet (URS) national championship from 1940-64, for a total of

4366 games.[12] We then supplemented this data with information regarding game ordering and

---

[11] Ties of RAW and thresholds are assumed to occur with zero probability.

[12] Given the smaller number of involved players, we do not expect playoffs in any tournament –

usually involving a multi-game match between two players -- to reflect the Soviet collusion

ply-count from Chessbase's Mega database 2006. An observation of a game includes the

tournament, the players' names, their ratings, which player was White, the ply number (half-

moves) at game conclusion, and the outcome. In light of the potential for player movement or

defection, whether a player is Soviet reflects the residence of a player at the time of a

tournament. We have complete observations for all FIDE games and about 40% of URS games.

The most common missing variables are ply-count and the round of the game, and we therefore

perform our ply-count regressions and fatigue-based ordered probit on smaller samples.

What makes this data set so valuable for our purposes is the continuity of the ratings

derivation. Ratings in chess that make use of rigorous statistics to produce good estimates of

relative player strength are now relatively common, but comparing ratings across different time

periods is often complicated by idiosyncratic changes (cf. Elo, 1968 for the pioneering

discussion). Sonas uses the same rating formula throughout our sample and updates this rating

monthly instead of annually, as is more common (cf. Sonas, 2005, and Sonas, 2006). Moreover,

retrospective grading allows him to establish rankings that are unbiased estimates of the "true"

relative strengths of players. This rating does require a minimum number of observed games to

construct. Games without Sonas chess-ratings for both players are dropped from the sample.

While this leads to the omission of a few Interzonal games, the vast majority of dropped games

are from URS championships. These omissions will presumably drive up the average observed

skill of Soviet players in URS championships, and thereby make our comparison to FIDE events

even more compelling.

---

hypothesis. Moreover, a two-person match format makes prearranged draws obviously

irrelevant.

Table 1 includes variable names, definitions, and summary statistics. Variables that are incorporated into White's relative advantage are at the top. As one would expect from the random way in which White is assigned, both RatingDif and SovietDif have mean zero. From the threshold variables below, we can see that 40% of our full sample's games are from FIDE tournaments and 6% of the total games involve two Soviets playing in a FIDE event. The ply-count variable indicates that the typical draw ended after 36 plays, as a play is composed of two plys (half-moves).

Results

We begin our evidence with a comparison of draw lengths in Table 2A. Draws in FIDE events occur after marginally fewer plays than draws in URS championships. More strikingly, draws in FIDE games that involve two Soviets occur substantially sooner than draws in FIDE games involving at least one non-Soviet. This raw data is then consistent with the draw-collusion hypothesis. A similar story appears upon examining draw rates, shown in Table 2B. Consistent with the Soviet collusion hypothesis, draws were likelier in FIDE events than in URS championships (51% vs 46%). This result, however, is also consistent with the possibility that all players acted more conservatively when they played in FIDE tournaments. We therefore consider the draw rates in FIDE events conditioned on whether both players in a game were Soviet. This result is much more striking: 67% of FIDE games involving two Soviets ended in draws, compared to a 48% draw rate for FIDE games in which at least one player was not Soviet. This, of course, matches the third prediction of the Soviet collusion hypothesis.

Our first regression builds upon the raw data regarding ply-counts. Using the sample of games that ended in draws and for which we observe ply-counts (n=2091), we run a least-squares regression of ply-count on the FIDE indicator and an interaction of the FIDE indicator and the

Both Soviet indicator. Those OLS estimates (asymptotic standard errors are in parentheses) are then

$$PlyCt = 75.87 - 3.22*FIDE? - 12.97*FIDE?*BothSov? + e$$
$$\quad\quad (1.00)\quad (1.63)\quad\quad\quad\quad (2.83)$$

Fit is poor, with $R^2 = 0.017$, but two conclusions can be drawn. One, there is some evidence that draws took marginally more plys in URS championships than in FIDE events. Two, there is strong evidence that draws involving two Soviets in FIDE events took significantly fewer plys than FIDE event draws involving at least one non-Soviet. The cartel's draws in FIDE events are estimated to occur eight moves sooner than draws in URS championships. In major chess tournaments playing a mere four or five additional moves (10-ply) at a critical stage of the middle game requires considerably more effort (and more risk). The results therefore indicate differences that are obviously of great substantive and not simply statistical significance.

Estimates from the ordered probit can be found in Table 3 (I-II). All parameters are precisely estimated. In addition to the obvious results of the difference in ratings being critical, results indicate the presence of a first-mover advantage ($\gamma^W < -\gamma^L$) and generally more conservative play in FIDE events than in URS events. Both predictions of the Soviet collusion hypothesis are also borne out. Soviets did outperform their ratings in FIDE events, and Soviets were likelier to draw against each other in FIDE events than in URS events. The magnitude of these estimates suggest that the average impact of the effort avoided by the Soviets in FIDE events was equivalent to about 68 points in the ratings.

We continue our estimation by considering the potential mechanisms through which Soviets outperformed against non-Soviets in FIDE events. Suppose that players began a tournament with a plan for effort expended for each game and draw-collusion helped Soviets by enabling them to limit their exertion against fellow Soviets and to concentrate more fully against

non-Soviets. Under such a mechanism, we expect to see no systematic difference in the extent of Soviet outperformance at different rounds of a FIDE tournament. If, however, draw-collusion allowed Soviet performance through the simpler mechanism of players being less fatigued as they advance, then we expect Soviet outperformance to be less early in a tournament and greater at a tournament's end.

As the necessary round data were scarce for URS events, we re-estimate the ordered probit model using only FIDE games (n=1751). In addition to dropping the FIDE indicator from the threshold variables, we also include a variety of proxies for the difference of players' fatigue levels. Table 3 (III-VI) displays results. Estimates shown in (III) replicate our earlier results omitting any FatigueDif variables. Columns (IV-VI) then separately consider the fatigue proxies of prior games played in the tournament (to capture the advantage of bye-rounds), prior plys (in 1000s), and prior games against fellow cartel members. We expect the first two variables to have negative coefficients and the third to have a positive coefficient. While all estimated coefficients have the expected sign, none greatly reduce the log-likelihood. Only the first two variables are significant at the 95% confidence level, and none are significant at the 99% confidence level. We therefore tentatively conclude that, while fatigue reduction may have played a complementary role in causing Soviet outperformance, the primary purpose of the Soviet cartel was to allow Soviet players to concentrate their effort more fully upon non-Soviet opponents.

Table 4 lists some implications of the full-sample, no-fatigue parameter estimates on the probabilities of game outcomes. First consider the baseline of two evenly matched non-Soviets meeting in a FIDE event. The model's estimates indicate that White has a 28% chance of winning, a 54% chance of drawing, and an 18% chance of losing. This compares to the model's implications of expected draw rates in games between two Soviets which mimic the raw draw

rates: 48% in URS events and 67% in FIDE events. Assuming Soviet collusion, the probability of an evenly matched Soviet playing White winning against a non-Soviet in a FIDE event rises from 28% to 38%.

Simulations

The evidence thus far does not speak to the question of whether this Soviet collusion had important impacts on tournament outcomes. For example, it could be that the Soviets were so dominant that this collusion only marginally increased the likelihood of some Soviet winning a FIDE tournament. To consider this question, we use the original estimates to simulate the five Candidates tournaments that occurred from 1950 to 1962 and determined the challenger to the world champion.

Observed characteristics and the model's estimates imply the probabilities of the three outcomes. Using a draw from the uniform distribution to simulate the outcome of each game, we then re-play each Candidates tournament 10,000 times. [13] The tournament's winner is the player with the most points (1 pt for win, ½ pt for draw, 0 pt for loss). [14] We conclude by considering a

---

[13] For example, an observed game's thresholds and relative advantage for White might imply a 10% chance of White losing, a 50% chance of White drawing, and a 40% chance of White winning. Letting e be the uniform draw, the simulated game ends in a loss if e<0.1, a win if e>0.6, and a draw otherwise.

[14] Two-way ties are resolved with the best of twelve format used in the 1950 Candidates between Boleslavsky and Bronstein, and ties involving more than two players are resolved using a double round-robin format. Ties at the end of these tie-breakers are resolved using a random number generator.

competitive counterfactual in which Soviets do not systematically outperform their ratings and they are no more likely to draw against Soviets than against non-Soviets.

Table 5 shows actual and simulated outcomes as well as player characteristics for the double round-robin 1950 Candidates in Belgrade. The limited range of the ratings gives some perspective regarding the size of the estimated Soviet collusive advantage (68 points). Soviet dominance is also apparent, as seven of the ten participating players are from the USSR. Under the collusive hypothesis, Smyslov was the favorite (winning 25% of the time), but the eventual winner Bronstein and Kotov were not far behind (each winning 22% of the time). From the Soviet cartel's perspective, a Soviet won the Belgrade Candidates 93% of the time. Under the competitive counterfactual, Najdorf's probability of victory rises from 3% to 13%, and the probability of a Soviet victory falls to 72%.

The 1953 Zurich Candidates (also a double round-robin) is depicted in Table 6. The number of participants increased from ten to fifteen in response to criticisms that limited Western involvement in Belgrade from visa and political concerns should not have lasting effects. Hence the successful players from the regular cycle were augmented by the strongest Western players that were felt by FIDE to have been arbitrarily cut off from participating in the previous cycle. By all accounts, Najdorf and Reshevsky were the strongest active players in the West and Euwe of Holland – though now past his prime -- was the only living ex-world champion. Retroactive grading has shown that Reshevsky was the favorite going into the 1953 Candidates' tournament.

Of all are simulations, Zurich shows the greatest difference between the probable winners when going from independent play to collusion. Though legendary for the quality of the games played and the high quality of the top competitors, continued concerns about Soviet collusion and political pressure against the Estonian Soviet Keres have dogged the reputation of this

tournament. Our calculations now suggest that the real loser from any collusion was likely to have been the American GM Reshevsky – the strongest American player in the decades prior to the rise of Bobby Fischer, and arguably the second strongest American player in the twentieth century. Our calculations indicate that he had a 27% chance of winning a fair tournament. With collusion, his chances fell to 8%. After the loss in Zurich, Reshevsky continued to play at a high level but never had a realistic chance of challenging for the world championship again.

Amsterdam 1956 (Table 7) is less interesting because the only non-Soviet in the top group was Oscar Panno who was never among the best half dozen in the world. However, it does illustrate the obvious point that Soviet dominance was not entirely a result of collusive behavior. Most of the world's top players came from the USSR. Simulations indicate that even under our competitive counterfactual, there was a 95% chance of a Soviet advancing in that tournament.

Yugoslavia 1959 (Table 8) saw the debut in the Candidates tournaments of Bobby Fischer, but he was only 16 years old and nowhere near his peak strength. Conversely, the young genius Mikhail Tal from Latvia had enjoyed a meteoric rise to become the leading player in the USSR and then the world. He was a rightful favorite. Moreover, in the case of young players with rapidly increasing ability, it is well-known that ratings have a tendency to underestimate their strength, which changes quickly as they approach their peak. Tal won the tournament convincingly and then went on to become world champion by defeating Botvinnik. However, poor health contributed to his losing the title back to Botvinnik in 1961. He never fully overcame his health problems though he remained one of the chess elite for two more decades.

Curacao 1962 (Table 9) was the famous tournament in which a mature Fischer accused

the Soviets of colluding – an accusation supported by Korchnoi after his defection. However,

Fischer's ratings suggest that he was not the ex ante favorite, even if his rating/performances put

him a few points shy of the leaders. Even if his true rating were higher (because Fischer had

been improving rapidly in the year or two previous to the tournament) Fischer's poor

form/performance in the early rounds of Curacao meant that he had no realistic chance of

winning. The Monte Carlo simulations do suggest, however, that he would have suffered from

any collusion since his no-collusion probability of winning was 19%, which dropped to 3% with

collusion. We did assume that all the Soviets were colluding and did not model the specific

claim of Korchnoi that collusion was a private arrangement of Keres, Petrosian, and Geller.

Conclusion

No one can know with certainty what sorts of pressures were imposed on Soviet players

during the heyday of the Soviet Union – especially in as politically significant a sport as chess.[15]

Some such as Korchnoi or Averbakh – both top Soviet GMs – have testified to the political

pressure faced by players to kowtow to the regime though others have questioned the accuracy

of these testimonies or the extent to which games were "fixed" (e.g. Kingston, 2002). Many of

the leading players of that period have now passed away and many important state documents

from the era have not yet been declassified. However, it is not hard to see how the elevation of

---

[15] Soviet emigré and international grandmaster Genna Sossonko tells of a story, perhaps

apocryphal, that "at one meeting of the Chess Federation, when the behaviour of a player who

had committed some misdemeanour was being discussed, [former military prosecutor and head

of the chess section of the USSR] Baturinsky said heatedly: 'During the war we used to shoot

such people'" (Sosonko, 2003, p. 101).

championship chess to a sport that exemplified the superiority of Homo Sovieticus would

support both formal and informal pressure on players to bend the rules. Even in a non-

ideological environment, it is possible that players from the same nation might have been

tempted to come to collusive arrangements in important tournaments. Given the highly delicate

nature of Soviet relations with the West in the later years of Stalin's rule and in the decade

following his death, it should not be surprising that adherence to fair play was not of the utmost

importance. Furthermore, a top Soviet player was in a unique position. He was able to travel

abroad – a highly restricted and desirable privilege – and he could earn foreign currency should

he succeed in foreign tournaments. Moreover, leading players were provided with generous

support from the state and enjoyed numerous other privileges not enjoyed by lesser players nor

by the general run of Soviet professionals[16].

Thus, the finding that the Soviets were more likely to draw amongst themselves in critical

FIDE tournaments than they were when playing other masters should not come as a surprise.

But our paper has been the first to provide strong statistical evidence in support of this result.

More important, we have shown that such collusion clearly benefited the Soviet players and led

to performances against the competition in critical tournaments that were noticeably better than

would have been predicted on the basis of past performances and on their relative ratings. The

likelihood that a Soviet player would have won every single Candidates tournament up to 1963

---

[16] Even as late as 1971 – long after the era of Stalin – performance in chess was treated with

utmost seriousness. After losing to Fischer 6-0 in 1971, GM Taimanov lost his title of "Merited

Master of Sports," was kicked off the Soviet national team, was forbidden to play in international

tournaments for two years, and was even forbidden from performing his secondary occupation as

a professional pianist (Plisetsky and Voronkov, 2005, p. 237).

was less than one out of four under an assumption of no collusion, but was higher than three out of four when the possibility of draw collusion is factored in.

As many chess writers have observed, Fischer was not a strong enough favorite to be severely harmed by the draw collusion in the notorious Candidates Tournament in Curacao 1962. Nonetheless, all non-Soviet players suffered from the effects of collusion. More significant is that the American GM Sammy Reshevsky seems to have been the greatest victim of collusive behavior. He was the ex ante favorite in the Zurich 1953 Candidates' Tournament and his second place finish in the tournament was strong enough that even small collusive effects might have meant the difference between success and failure. By all accounts, Zurich was Reshevsky's last and perhaps best chance to play a match for the World Chess Championship.

In addition to the relevance of our results for the history of chess, the addition of draws to the possible outcomes of a contest suggests interesting modifications to the standard tournament literature. Almost all of the existing research work in the economics literature has focused on competitions where the scores are assumed to be monotonic in effort (e.g. golf) or where the outcomes of a match are either a win or a loss (e.g. tennis or most team sports). The possibility of a draw outcome and the fact that the choice of strategy might not affect the expected value of a match but might affect the distribution of outcomes (more draws with fewer wins and losses vs a higher chance of a win with a higher risk of a loss) poses interesting problems from a theoretical and empirical standpoint (cf. Hvide, 1999). Future research can be devoted to exploring the theoretical implications of this modification to the standard model. One can also ask how the possibility of strategies that "keep the draw in hand" might affect the applications of the tournament literature to structuring incentives in strategic competitions or in designing incentive pay packages in managerial hierarchies.

Appendix I

Official World Chess Champions and Their Challengers 1948-1990

Year [winners in bold]	Champion	Challenger	
1948	**Botvinnik**	Initial championship tournament	
1951	**Botvinnik**	Bronstein	[tie]
1954	**Botvinnik**	Smyslov	[tie]
1957	Botvinnik	**Smyslov**	
1958	Smyslov	**Botvinnik**	
1960	Botvinnik	**Tal**	
1961	Tal	**Botvinnik**	
1963	Botvinnik	**Petrosian**	
1966	**Petrosian**	Spassky	
1969	Petrosian	**Spassky**	
1972	Spassky	**Fischer**	
1975	Fischer	**Karpov**	[default]
1978	**Karpov**	Korchnoi	
1981	**Karpov**	Korchnoi	
1984/85	Karpov	Kasparov	unfinished
1985	Karpov	**Kasparov**	
1986	**Kasparov**	Karpov	
1987	**Kasparov**	Karpov	[tie]
1990	**Kasparov**	Karpov	

Except for 1948 all championships were 2 player matches of many games.
All Soviet players except Fischer (USA).
Korchnoi defected in 1976 and eventually came to represent Switzerland but not in 1978.
In the event of a tie, the champion retained the title.
Until 1963, the champion had the right to an automatic rematch if he lost. But there was no rematch rule 1963-1975.
The rematch clause was reinstated with Karpov.
Fischer declined to defend his title in 1975 over a dispute with FIDE.
The 1984/85 Karpov Kasparov match was broken off and a new match played in 1985.
